Credit Misallocation During the European Financial Crisis[*]

PRELIMINARY AND INCOMPLETE

Abstract

Do banks with low capital extend excessive credit to weak firms, and does this matter for aggregate efficiency? Using a unique data set that covers almost all bank-firm relationships in Italy in the period 2007-2013, we find that, during the Eurozone financial crisis: (i) Under-capitalized banks were less likely to cut credit to non-viable firms. (ii) Credit misallocation increased the failure rate of healthy firms and reduced the failure rate of non viable firms. (iii) Nevertheless, the adverse effects of credit misallocation on the growth rate of healthier firms were negligible, and so were the effects on TFP dispersion. This goes against previous influential findings that, we argue, face serious identification problems. Thus, while banks with low capital can be an important source of aggregate inefficiency in the long run, their contribution to the severity of the great recession via capital misallocation was modest.

Keywords: Bank capitalization, zombie lending, capital misallocation

1   Introduction

An important dimension of financial crises is a weakened banking sector. There is a widespread perception in the policy debate that under-capitalized banks can prolong depression by misallocating credit to weaker firms in the verge of bankruptcy and restraining credit to healthy borrowers ("zombie lending"). This perception is supported by evidence for Japan during the "lost decade" (Caballero et al. 2008) and, more recently, for the Euro area during the financial crisis (Acharya et al. 2016). Due to data and methodological challenges, however, assessing the consequences of a weakened banking sector on credit allocation and real economic activity is difficult. Moreover, during a recession not all economic effects of zombie lending are necessarily bad for the healthy part of the economy. Extending credit to very weak firms keeps them alive and may prevent layoffs. This in turn can mitigate the adverse aggregate demand externalities that are so important during a recession (Mian et al. 2015). Firms closures can disrupt input-output relationships that, at least in the short run, can be difficult to substitute for (Barrot & Sauvagnat 2016). In this paper, we add to the literature by improving both in terms of data quality and of identification framework. As we show below, these modifications lead to conclusions that differ substantially from the received wisdom.

We explore the extent and consequences of credit misallocation in Italy during and after the Eurozone financial crisis. We ask two main questions. First, what bank characteristics are more conducive to zombie lending? Second, what is the cost of zombie lending in terms of lost economic activity and misallocation of real resources? Italy is an ideal testing ground for these issues, because the financial crisis induced a very deep and long recession, that left a cumulative drop in GDP of almost 10%. This caused a very large increase in non-performing loans (from 5.8% of outstanding bank loans in December 2006 to 16% in December 2013), and a prolonged contraction in bank credit (see Figure 1). Moreover, unlike other Eurozone countries, Italy did not inject public funds to recapitalize its banking system nor it created a bad bank to absorb the non-performing loans. As a result, Italian banks remained saddled with a large fraction of bad loans, and several banks struggled to meet the stricter capital requirements imposed by regulators in the aftermath of the crisis. The problem persists today, and it is one of the major current policy challenges in Italy.

In short, these are our main findings. Under-capitalized banks are more likely to keep lending to zombie firms during the financial crisis, compared to stronger banks. This affects firms survival and exit: in the areas-sectors where lending is predominantly done by weaker banks, zombie firms are more likely to survive while non zombies are more likely to go bankrupt. Nevertheless, and contrary to previous findings, we do not find

evidence that bank under-capitalization hurts the growth rate of healthy firms.

We use a unique data set that covers almost all bank-firm relationships in Italy for the period 2007-2013. We observe all incorporated firms, including small ones. Most of the previous literature instead considered only listed firms. In addition to detailed information on firm-bank relationships, we also have access to firms and banks balance sheets. We focus on the most extreme form of credit misallocation, namely, loans granted to firms that clearly are no longer viable – *zombie firms*. We define as zombie a firm that is highly indebted and for which the returns on assets have been systematically below the cost of capital of the safest firms (we experiment with alternative definitions to assess robustness). As shown in figure 2, credit to zombie firms dropped faster than credit to healthier firms during the first part of the crisis, but the opposite was true from 2011 onwards, when low capital became a pressing problem for several Italian banks. This suggests that credit was not reallocated away from zombie firms.

To study what bank characteristics are conducive to zombie lending we regress the growth rate of granted credit at the firm-bank level on various indicators of banks' solidity, using the regulatory capital ratio as the preferred one. The identification challenge in this type of regressions is that the observed granted credit is the result of both demand and supply of credit. To single out the supply effects, we exploit the fact that Italian firms typically borrow from more than one bank. This enables us to compare banks with different degrees of capitalization that lend to the same firm, controlling for firm-year fixed effects. As first argued by Khwaja & Mian (2008), this allows to control for any effect coming from firms' credit demand, such as a higher demand from zombie firms, and to interpret the coefficients in terms of credit supply effects.

We depart from the previous literature when we analyze the consequences of zombie lending on healthy firms. Typically, this question is addressed by regressing indicators of firm performance on the share of zombie firms in the sector in which the firm operates. The main challenge to identification is that an adverse sectoral shock both increases the share of zombies and affects firms performance. Following Caballero et al. (2008), the standard approach is to include fixed effects at the sector-year level in the regression, so as to fully control for aggregate shocks, and to allow zombie and healthy firms to be differentially affected by a larger share of zombies in the sector. This approach can only estimate the *relative* effect of the share of zombies on healthy firms compared to zombies, however, as the share of zombies itself is absorbed by the dummies. Estimating a relative effect is not very informative, because we care about the absolute effect on healthy firms, and zombie lending is likely to improve the performance of zombie firms. Moreover, while it accounts for aggregate shocks, this approach neglects a second, and more subtle, identification problem. A negative correlation between the share of zombies in a sector and the relative

2

performance of healthy vs zombie firms is interpreted as evidence of adverse spillovers from zombies to healthy firms. But this rests on the assumption that, in the absence of spillovers from zombies to healthy firms, aggregate shocks have the same effect on the two groups of firms. We show that this assumption is violated in very standard settings with heterogeneous firm performance. For example, when performance follows a normal distribution, aggregate shocks that shift the entire distribution to the left mechanically generate a negative correlation between the share of zombies and the relative performance of healthy vs zombie firms, even in the absence of any spillover effects.

To cope with these issues, we replace the share of zombies with a measure of banks capitalization. Since both bank lending and production are geographically concentrated, we take the relevant market to be the province-sector in which a firm is located, and study how the average capitalization of banks active in a given province-sector affects firms performance within the same province-sector. Banks are typically active in several province-sectors, and exposure to a single province-sector is very low: on average banks are active in about 48% of sector-provinces (the median is very similar). Thus, bank capitalization is unlikely to be correlated with shocks in the province-sector, and we can take it as exogenous with respect to shocks that shift the distribution of firms. Moreover, given the exogeneity of banks capitalization, we can estimate regressions without province-sector-year fixed effects and recover the absolute (and not just relative) effect of bank capitalization on the performance of healthy firms.

These are our main results. In terms of lending, we find that low-capital banks engaged in significantly more zombie lending, compared to other banks. More precisely, between 2008 and 2013 bank credit drops by almost 8% every year on average. But banks with a capital ratio below the median provide 1.5 percentage points of additional yearly credit growth to zombie firms, compared to stronger banks (a 20% increase relative to the average). The result is robust to the definition of zombie firm and to the measure of bank capital. There is also evidence that the effect is non-linear and it is larger for the much weaker banks. Results are similar if we look at the extensive margin: the probability of closing a credit relationship with any firm drops by 1 percentage point if the bank regulatory capital ratio is below the median, and it drops by a further 0.7 percentage point if the firm is a zombie and bank capital is below the median. Low-capital banks are also less likely to classify their loans as bad, whether they are loans to zombie firms or to any firm. All these results point to the conclusion that weak banks misallocate credit, because they are more likely to keep lending to non viable firms.

We next explore the adverse real effects of credit misallocation on healthier firms and on aggregate economic activity. We start by considering the intensive margin, namely how zombie lending affects the growth of existing non-zombie firms. Our central result here

3

is that bank under-capitalization has only negligible (absolute) effects on the growth of healthy firms during the recession. This holds for several indicators of economic activity, such as the wage bill (a proxy for employment), the capital stock and revenues. The reason is that, although bank under-capitalization hurts the relative performance of healthy vs zombie firms, it also improves the growth rate of zombies. As a result, the absolute effect on healthy firms is negligible. This finding may seem surprising, in light of the received wisdom from the previous literature. A priori, it is argued, weak banks that engage in zombie lending hurt healthy firms in two ways: first, by reducing bank credit available to the rest of the economy; second, because lending to non-viable firms is equivalent to a subsidy, it hurts their competitors in product and input markets. But zombie lending may also have positive economic effects during a recession: because it does not force inefficient firms to shrink or to exit, it could mitigate adverse aggregate demand and input/output externalities. This last mechanism has generally been neglected by the literature, but the data suggests that it may be empirically relevant.

We then explore the extensive margin, namely the effect of bank capitalization on the survival rates of zombie and non zombie firms. In line with the results on credit allocation, we find that weak banks influence the composition of bankruptcies. Zombies are more likely to survive, and healthy firms are more likely to fail, in province-sectors where lending is predominantly done by banks with a capital ratio below the median. To assess the magnitude, consider an injection of capital in the weak banks so as to bring their capital ratio to the median level. This counterfactual exercise would increase the failure rate of zombies by 0.4% and reduce the failure rate of non zombies by 0.2%. This represents a reduction of one tenth in the failure rate of healthy firms in the period.[1]

Finally, we ask whether bank under-capitalization is positively correlated with (revenue based) TFP dispersion in the province-sector. As shown by Hsieh & Klenow (2009), in the absence of frictions in the inputs market, revenue TFP should be equalized across firms. Thus TFP dispersion can be interpreted as revealing the presence of some frictions or misallocations in the input markets The data show that there is a positive association between low bank capitalization and aggregate TFP dispersion, but only in the presence of a large fraction of zombie firms.

A weak banking sector is often identified as one of the key causes of low economic growth in Southern Europe and in Italy in particular, since the onset of the financial crisis (e.g., Acharya et al. 2016). This inference is only partially supported by our findings. There is clear evidence that, during the crisis, weaker banks have kept lending to

---

[1]Our finding that low bank capital has much larger effects on the extensive than on the intensive margin is in line with the findings of Midrigan & Xu (2014), who study the impact of credit frictions on TFP through both margins.

non-viable firms to a greater extent than stronger banks. But the adverse economic consequences of this credit misallocation are only evident on the exit rates of non zombie firms, and not on their growth rate. To quantify the aggregate effects, consider an injection of capital of 4 billions Euros in the weaker banks. This is the amount that, as of 2012, would bring their capital ratio to the median level. Inserting our estimates in a simple evaluation scheme, this injection would increase the yearly output growth by at most 0.1% during 2008-13, and it might even turn negative, depending on the relative productivity of zombies vs non zombies. During this period, output in our sample on average shrank by almost 2 percent per year. The contribution of zombie lending to this negative performance is therefore less then 5%, and comes almost entirely from the extensive margin and the composition of firms exits.

These findings contribute to the current policy debate on the importance of bank capital and on the consequences of a large stock of non-performing loans on credit supply and its allocation (IMF 2016). They suggest that the main reason for injecting capital into a weak banking sector is not so much to alleviate the recession or shorten its duration, but rather to prevent productive inefficiencies and possibly to facilitate the recovery once it is in place.

The outline of the paper is as follows. Section 2 outlines the related literature. Section 3 describes the data and our methodology to define zombie lending. Section 4 describes the empirical strategy and asks which types of banks engage in zombie lending, while the real consequences of zombie lending are explored in section 5. Section 6 evaluates the aggregate implications of low bank capitalization, and section 7 concludes.

2 Related literature

Misallocation of credit has been proposed as an explanation for the prolonged stagnation of the Japanese economy after the real estate crisis of the early 90s. Following Hoshi (2000), a large literature attempted to quantify the phenomenon of "zombie lending". Peek & Rosengren (2005) document that under-capitalized banks kept lending to weak firms during the Japanese crisis. Caballero et al. (2008) study zombie lending during Japan's "lost decade". They find evidence of lending to zombie firms by weaker banks. They also investigate the effect of zombie lending on the growth of healthy firms relative to zombies, finding a large relative effect. Subsequent studies of the Japanese case have used different definitions of zombie firms and often a longer time span. Results are mixed, suggesting that the impact of zombie lending on economic performance may have been overstated (Ahearne & Shinada 2005, Fukao & Ug Kwon 2006, Fukuda & Nakamura 2011). More recent work explores the effectiveness of bank bailouts during the Japanese crisis,

finding that capital injections that are too small both fail to increase the supply of credit and encourage the evergreening of nonperforming loans (Giannetti & Simonov 2013).

With reference to the European crisis, it is often argued in the financial press that banks weakness and an inefficient allocation of credit may have prolonged the stagnation and delayed the recover. Yet, surprisingly little evidence on zombie lending in Europe is available. Acharya et al. (2016) use syndicated loan data to study banks behavior after the "whatever it takes" announcement by Mario Draghi. This policy turn led to a drop in yield on sovereign bonds, generating an increase in trading profits for banks. Under-capitalized banks used the extra profits to lend to industries with a higher share of zombie firms. Acharya et al. (2016) also find that a larger share of zombies hurt the growth of healthy firms in the same industry and country, relative to zombie firms. McGowan et al. (2017) show that the resources sunk in zombie firms have risen since the mid 2000s in OECD countries, with negative consequences on the performance of non-zombies. Albertazzi & Marchetti (2010) identify zombie firms as those with low TFP, and look at the dynamics of credit supply in the year following the default of Lehman Brothers. They find no evidence of zombie lending or of loan evergreening.

A large literature has discussed the relevance of credit frictions as a driver of the misallocation of factors of production. Hsieh & Klenow (2009) propose a standard model of Cobb-Douglas production with monopolistic competition in which the dispersion of (revenue) TFP measures the extent of the misallocation of resources. They estimate a large effect of misallocation on aggregate productivity in India and China compared to the United States. While they do not explicitly measure the impact of credit frictions, these are among the most likely sources of frictions that drive the misallocation. Other works suggest a more mixed picture. On the one hand, Moll (2014) shows that the impact of financial frictions on TFP are large and persistent, i.e. they cannot be undone by self-financing of firms, and Yang (2011) shows that micro-level frictions, including credit frictions, can generate sizeable aggregate TFP losses by distorting the selection of new entrant firms. On the other hand, Midrigan & Xu (2014) suggest that financial frictions affect aggregate TFP by inducing an inefficient entry and exit of firms, while the impact on the intensive margin is small. Borio et al. (2016) use a long time series at the country-industry level and show that credit booms tend to undermine productivity growth by inducing reallocation of labor towards sectors with low productivity growth. Finally, Asker et al. (2014) argue that, in the presence of adjustment costs and a volatile productivity process at the firm level, it is not possible to identify the extent of misallocation from purely cross-sectional data.

A growing literature studies the impact of misallocation of resources on GDP and TFP growth after financial crises, and generally finds large negative effects (Barnett et al.

6

2014, Di Nola 2015). Gopinath et al. (2015) document a significant increase in productivity losses from capital misallocation in Southern European countries, most notably Spain. They show that the drop in real interest rates following the introduction of the Euro led to a misallocation of capital inflows toward firms that have higher net worth but are not necessarily more productive. Gamberoni et al. (2016) use industry-level data from 5 European countries and find that restrictive bank lending standards and heightened demand uncertainty led to capital misallocation, but the allocative efficiency of both capital and labor improved during the Great Recession. These general patterns are confirmed by two recent papers that focus on the case of Italy (Calligaris et al. 2016, Linarello & Petrella 2016).

Our work contributes to this literature in several ways. First, we use a comprehensive dataset representative of the whole population of banks and firms, that includes both listed and unlisted firms. This is important when it comes to quantifying the relevance of zombie lending. Data covering only listed firms, or only syndicated loans can hardly provide a good basis to quantify the relevance of zombie lending and its impact on the real economy. Second, thanks to the richness of our data set, we can identify the presence of zombie lending by exploiting firms that borrow from more than one bank. This allows us to quantify the extent of zombie lending after controlling for firm demand for credit and more generally for firm unobserved characteristics. Third, we propose a new and more reliable definition of zombie firm, that takes into account both efficiency (return on assets) and financial fragility (indebtedness before the crisis). Fourth, when assessing the consequences of bank under-capitalization on aggregate economic efficiency and growth, we can distinguish between the intensive margin (growth of existing firms) and the composition of bankruptcies, documenting how the most important aggregate effects of bank weakness operate through the latter channel. Last, and perhaps most important of all, we estimate the *absolute* effect of bank under-capitalization on the growth of healthy firms, and not just a relative effect on the growth of healthy vs zombie firms. This is a significant departure from the most influential papers in the literature, because we find that, while the relative effect is negative and highly significant, the absolute effect is negligible. We also show that the identification approach used in the literature to estimate the real effects of zombie firms is weak, because common shocks to firm performance that increase the share of zombie firms typically have differential effects on zombie and non-zombie firms.

3 The Data

The paper uses two samples. In the first one we study what types of banks engage in zombie lending, exploiting data on bank-firm relationships. Only firms that borrow

from at least two banks are included in this sample. In the second sample we explore the consequences of zombie lending. Here all firms are included, irrespective of their borrowing status. In both samples, we restrict attention to non-financial firms excluding agriculture. Both samples are obtained matching three data sources: the Firm Register (Cerved), that contains balance sheet information of *all* limited liability companies incorporated in Italy– as opposed to listed firms only, typically used in the literature; the Credit Register, that contains information on all loans by Italian banks; and the Supervisory Reports collected by the Bank of Italy, that contain balance sheet data on all Italian banks. In this section we describe the first sample. The variables used in the second sample are defined and described in Section 5.

Combining the three data sources, we obtain loan-level information on all relationships between Italian banks and firms, matched with balance sheet information of both firms and banks. Loans are divided into three broad categories: overdraft loans (uncommitted credit lines), term loans (these include leasing, mortgages and committed credit lines), loans backed by receivables. To avoid drawing inferences from very small loans, we drop credit relationships with granted amounts below 30,000 Euros and we exclude mutual banks, as these are subject to highly specific regulations in their lending and governance.[2] Moreover, because of our identification strategy, we only retain firms that have credit relationships from at least two banks in a year. This leaves us with a sample of N observations for which we have detailed information on firm and bank balance sheets, corresponding to M firms and K banks. This is a very comprehensive sample, especially in terms of firm size. Median firm assets are ?? million euros, indicating that a large fraction of small firms is included. Summary statistics are described in the next subsection.

Our main sample spans the period 2008-2013, namely the years of the great recession (2008-2009) and the sovereign debt crisis (2011-2013). However, for some variables we use firm balance sheet data going back to 2002, and we also repeat the econometric analysis for the period 2004-2007).

3.1 What is a zombie firm?

We define as zombie a firm for which the expected marginal return of capital is below the risk adjusted market cost of capital. Lending to zombie firms thus results in misallocation of capital, that could earn higher returns (and produce more output) elsewhere. Since we don't observe the expected marginal return of capital nor the risk of each firm, we rely on alternative measures of what is a zombie firm, and check that our results are robust to these alternative definitions. All these alternative measures combine indicators

---

[2]They can only lend in their geographic area and primarily to their shareholders (who also must be local residents).

of low profitability and of high default risk. From a lender's perspective, both the debtor's expected profits conditional on surviving and default risk matter, since both determine the expected return on the loan.

Our preferred indicator of profitability is the return on assets, defined as Earnings Before Interest, Taxes (EBIT) over total assets. EBIT is what is left of revenues after paying labor and intermediates, and deducting the replacement of capital so that its ratio to capital invested is the average gross return on capital.[3] Ideally, we would like to measure expected future profitability. Since this is not available, we rely instead on a three year moving average of the return on assets. We thus define the variable *return on assets* (ROA) as the three year moving average of EBIT over total assets. We compare ROA to a measure of the cost of capital for the safest borrowers in the sample. This is computed as the average interest rate charged on new term loans granted to the safest firms. To reduce time series fluctuations related to changes in the policy rates, here too we use a three years moving average. The safest firms are defined as those having an Altman Z-Score of either 1 or 2 - the Z-score varies from 1 (safest) to 9 (riskiest). This measure of the cost of capital is called *prime rate* (PRIME).

As a measure of default risk, we rely on leverage. Highly indebted firms are obviously more at risk of default, so that a lender should be less willing to extend them credit, controlling for expected returns. We define *leverage* as total financial debt over total assets. Total financial debt excludes debt towards shareholders, typically more akin to equity.

In our default definition, we classify a firm as zombie in any given year if, in that year, ROA is below PRIME, and if leverage exceeds 40%. This threshold corresponds to the median value of leverage in 2005 in the sample of firms that exited during 2006-2007 (i.e. just before the financial crisis), and that during the previous two years had ROA< PRIME at least once. We checked that the share of zombies varies little and continuously as we vary the leverage threshold between the 40-th and the 60-th percentile of the distribution, implying that our definition of zombie is not particularly sensitive to the numerical value of the selected threshold.

Figure 4 shows the time evolution of the share of zombies together with the evolution of GDP growth. The share of zombies reaches a maximum in 2009, when GDP contracted by almost 6%. It declines slightly in the following two recovery years and it increases again in 2012, when GDP growth turns negative again, dropping only slightly in 2013 as the contraction in GDP gets smaller.

---

[3]For the Cobb-Douglas technology with constant returns to scale, this is exactly equal to the marginal product of capital. However, the depreciation and amortization of capital may be affected by tax incentives. For this reason we also used EBITDA, earning before interest, taxes, depreciation and amortizatio and results are qualitatively the same. The share of zombie firms in the economy is lower, though.

We also experiment with a different measure of profitability, comparing EBIT to interest expenses to determine creditworthiness. Clearly, debt is unsustainable if interest expenses exceed EBIT for a prolonged period of time. Specifically, we define the variable *RATIO* as the ratio between the three year moving average of EBIT and the three year moving average of interest expenses. A firm is defined as a zombie in a given year if in that year the variable *RATIO* is below 1 and if its leverage is above 42.5% (consistently with the previous definition of zombie, this threshold is the median of leverage in 2005 in the sample of firms that exited during 2006-2007 and had $RATIO < 1$ in 2004 and/or 2005). The dummy variable corresponding to this definition of zombie firm is called *Zombie 2*. We also experiment with a third definition, called , *Zombie 3*, which is defined as *Zombie 1*, except that we impose the additional condition that revenues do not increase for the next 3 consecutive years. This is to avoid defining start-ups as zombies.

The three definitions overlap significantly, although the second one is more stringent: about 18% of firms are classified as zombie in the first definition, and about 10% in the second one. The definition based on the ratio of EBIT to Interest Expenses (*Zombie 2*) is almost a strict subset of that based on the comparison between ROA and the prime rate. Only 0.2% of firms are classified as zombies according to definition 2 and non-zombie according to definition 1. The opposite occurs instead in 7.1% of the cases. Overall, we prefer definition 1 since it is based on an economic notion of credit misallocation, namely low returns on capital, but we check the robustness of our results to the more restrictive definition 2.

These two definitions classify as zombies firms that pass the established thresholds of low profitability and high leverage. While useful from a descriptive viewpoint and easy to interpret, there is some arbitrariness in the choice of the thresholds. Moreover, one could argue that the status of zombie would be better described by a continuous rather than a dichotomic variable. For this reason, we also construct two continuous indicators of zombie firms, by taking the first principal component of the two variables on which the dichotomic indicators are constructed. Specifically, *PC ROA Leverage* is measured as the first principal component of leverage and ROA, while *PC EBIT/INT Leverage* is measured by the first principal component of leverage and the ratio of EBIT over interest payments. For the continuous variables, the share of variance accounted for by *PC ROA Leverage* is 62%, while that accounted for by *PC EBIT/INT leverage* is 54%.

Observable outcomes associated with zombie firms are very different from those of healthy firms, confirming the plausibility of our definitions. First, the status of zombie firm is highly persistent. If a firm is classified as a zombie in period t, it has 72% probability of still being a zombie next period, and there is little difference between the pre-crisis and the crisis years. Second, credit to zombies is much more likely to be cut

by the average bank: the proportion of terminated relationships with zombies is 14%, against 9% for non-zombies. Third, the share of zombie firms that exited because of default and bankruptcy is 12.8%, that of non-zombies 3.3%. Fourth, revenue growth is much slower for zombie firms than for non-zombies. The 3-year average growth rate of revenues (weighted by firms' assets) is -3.53% for zombies, while it is 1.70% for healthy firms. This is important to reduce concerns that we may be classifying high-growth firms as zombies. For example, a start-up might have high leverage and negative profits because of high investment, but this might be due to high growth opportunities. It turns out that this is not the case in our data, indicating that our definition of zombie is effectively identifying firms with grim prospects.

3.2   Variables used in the credit regressions

In Table A2 in the Appendix we report descriptive statistics of the variables used in the credit regressions. In terms of dependent variables, we use the growth of credit, a dummy for the break-up of the credit relationship and various indicators of the decision of the bank to classify a loan as problematic. Average credit growth is -8.06% in our 2008-13 sample (it was 5.3% in the previous four years)to, while the share of zombie firms is 19%.

Our key regressors are indicators of banks strength. The main measure of bank strength is the regulatory capital ratio. This is defined as the ratio of total capital (the sum of Tier 1 and Tier 2 capital) to risk-weighted assets. Regulation prescribes that banks maintain this ratio above 8%. Higher capital identifies financially stronger banks. Table A2 in the Appendix shows that average and median capital ratio are around 11%, reflecting the efforts at rebuilding bank capital during the crisis. Figure 5 illustrates how zombie firms are distributed between banks, according to their capital ratio. Banks with a capital ratio in the bottom quartile of the distribution have a substantially higher share of zombies out of total borrowers. Banks in the second quartile have a share that is lower than that in the first by still higher than that of last two quartiles, which have similar values. This suggests that the relationship between zombie lending and capital ratio is non-linear: weak banks are more likely to engage in zombie lending, but as the capital ratio increases substantially above the regulatory threshold, the relationship between capital ratio and zombie lending vanishes. To capture this non linearity, our preferred indicator of a weak bank is a dummy variable which equals 1 if in year t the capital ratio is below 10.99%, corresponding to the median of the distribution in 2008 (the starting year of our sample). We call this variable *LowCap*. Given that the median is stable over time, using year-specific medians delivers similar results.

Table A2 in the Appendix shows that the variable *LowCap* is one in 46% observations.

This suggests that banks with fewer borrowers (smaller banks) suffered a more severe capital shortfall during the crisis. We experiment with alternative indicators based on the capital ratio, such as the level of the capital ratio itself or a dummy for banks just below the regulatory threshold of 9%. We also use an alternative measure of financial strength, that is the ratio between Tier 1 capital, the capital with the highest risk-absorption capacity, and risk weighted assets. Descriptive statistics for all these variables are in Table A2 in the Appendix.

Other bank characteristics may be relevant for lending. For this reason, in the regressions we include a set of standard controls for lending regressions (Khwaja & Mian 2008, Iyer et al. 2014): the liquidity ratio, namely the ratio of cash plus government securities to total assets; the ratio of interbank deposits to total asset; bank profits divided by total assets; and bank size, measured by the log of total assets. Appendix Table A2 also shows that the average firm borrows over one quarter of its bank credit from a single bank, and that approximately one quarter of total credit is granted through credit lines.

4 Who lends to zombie firms?

Why would any bank want to lend to a non-viable firm? A strong bank, with large equity and sound management, would never want to do that. The period under consideration does not meet these ideal conditions, however. Capital requirements were raised repeatedly and several banks had capital shortfalls. But raising capital was very difficult and expensive in the midst of the financial and sovereign debt crisis. Delaying recapitalization until aggregate economic conditions improved may have been preferable for banks, for two reasons. On the one hand, an economic recovery would reduce bank losses (on loans and other bank assets) and thus also the size of the necessary recapitalization, thanks to future retained earnings. On the other hand, raising fresh capital would be cheaper once the crisis was over. This created an incentive to hide losses for all banks, but particularly for those with less regulatory capital who faced more pressing recapitalization requirements.

Our main hypothesis, therefore, is that zombie lending reflects an attempt to hide losses by banks who sought to avoid or delay recapitalization imposed by regulators. Faced with a zombie creditor, a bank had to choose between rolling over the credit ("evergreening"), or recognizing it as non-performing and writing off some capital. The more pressing was the capital requirement, the more likely it is that credit extension was the preferred option.

This logic has a number of empirical implications.

- First, banks with low capital are less likely to cut credit to zombie firms, to terminate

a credit relationship with a zombie firm, and to classify loans to zombie firms as non-performing, compared to banks with adequate capital.

- Second, the relevant measure of capital is related to the nature of the capital requirements. If recapitalization is mainly imposed by regulators, then regulatory capital is the relevant measure of bank strength. If instead the pressure to recapitalize is manily coming from financial markets, then other indicators of bank strength, like leverage, may be more strongly correlated with zombie lending.

- Third, evergreening is more likely if the bank accounts for a large share of credit to the zombie firm. The reason is that in this case the firm is less likely to find alternative sources of financing, and hence debt repayment is less likely.

Zombie lending could also reflect incentives to "gamble for resurrection", rather than the attempt to hide losses. For a bank with low equity, limited liability implies that shareholders fully capture the benefits of upward risks, but only bear a small fraction of the downward risk. Hence they have an incentive to finance very risky projects at high interest rates; if the gamble succeeds they gain, otherwise losses are born by others (bank creditors or taxpayers in case of a bailout). We can discriminate between these hypotheses by looking at the terms of zombie lending. If interest rates charged to zombie firms are low, then the bank is extending credit at subsidized rates in order to hide losses. High interest rates, instead, would be evidence that the bank is gambling for resurrection.

In the remainder of this section we test these predictions, and explore which bank features and loan conditons are associated with zombie lending.

4.1 Empirical strategy

Our goal is to estimate which bank features are conducive to zombie lending. We do it in the following regression framework:

$$\Delta b_{ijt} = \beta_0 + \beta_1(Z_{it} * LowCap_{jt}) + \beta_2 \mathbf{X_{ijt}} + Dummies + \eta_{ijt} \qquad (1)$$

where Δb_{ijt} is the log difference in total lending of bank j to firm i between year t and $t+1$; Z_{it} is the zombie 0/1 indicator; $LowCap_{jt}$ is a dummy equal to one if the capital ratio of bank j at time t is below the median in 2008 (or alternative measures of bank capital); $\mathbf{X_{ijt}}$ are other controls at the firm and bank level (that also include Z_{it} and $LowCap_{jt}$); $Dummies$ are different sets of dummy variables used in different specifications. To test the predictions discussed above, we also replace Δb_{ijt} with other dependent variables, such as dummy variables for whether the credit relationship survives and for whether the loan is classified as non-performing by the bank, and the interest rate charged on the

loan. Our coefficient of interest is β_1, that captures the effect of a bank's capital ratio on the propensity to lend to zombies. A positive coefficient indicates that weaker banks lend relatively more to zombies, compared to stronger banks. To account for potential correlation in the residuals at the level both of the bank and of the firm, standard errors are always double clustered at the bank and firm level.

The main identification issue is that observed credit also depends on credit demand by firms. Firms are not randomly matched to banks. The correlation measured by β_1 could be due to matching between weak banks and weak firms for reasons other than the banks' capital ratio. For example, some banks could have specialized in lending to firms that were more severely hit by the crisis, which in turn led to a deterioration in the banks' financial position. In this case, causality would go from firms to banks rather than the other way around. The richness of our data allows us to properly address this issue. First, we use changes in credit granted, rather then levels, so as to consider the dynamics of credit evolution rather than a stock measure of exposure. This does not eliminate all concerns, because zombie firms, possibly more likely to be matched to weak banks, might demand more credit during the crisis, compared to healthy firms. We thus follow the identification strategy proposed by Khwaja & Mian (2008). A well-known feature of the Italian lending market is that firms tend to borrow from different banks simultaneously (Detragiache et al. 2000). In our data firms have 3.3 lending relationships on average. This allows us to include a full set of firm-year dummy variables. These dummy variables control for any potential effect coming from firm-level time varying shocks to credit demand and therefore account for all the unobserved heterogeneity at the firm-year level.[4] Our estimates are only based on within firm-year variations in credit growth across banks with different degrees of financial strength. Thus, the inclusion of firm-year dummy variables rules out any demand driven potential correlation between unobservable determinants of credit growth and measures of capital intensity of banks.

A second identification concern is that the bank capital ratio could be correlated with unobserved bank features that influence zombie lending, such as management practices or features of the banks' balance sheet. For this reason, we include a full set of bank dummies, to account for all potential fixed unobserved heterogeneity at the level of the bank, as well as several observable and time varying banks' characteristics, potentially correlated with the capital ratio and with lending policies, such as bank profitability, liquidity and liability structure (more details are provided in context).

There remains a final concern. Although total credit demand by the firm is controlled by firm-year fixed effects, its partition across banks could reflect unobserved firm heterogeneity correlated with bank features. For instance, zombie firms could demand more

---

[4]Firm-year dummies also account for all observed heterogeneity, making firm controls redundant.

credit from weaker banks because of stronger historical ties with such banks. Note that our dependent variable is credit growth, rather than the stock of credit, which reduces the relevance of this issue. Nevertheless, to cope with this concern, we also control for some observable features of the bank-firm match, such as the importance of the individual bank in the total bank debt of the firm, and the share of credit granted through a credit line. For example, it might be easier to cut credit growth if it takes the form of a credit line, whose conditions can be modified unilaterally by the bank at any time, or if the bank accounts for only a small fraction of total firm credit. Thus, we define $share$ $bank_{ijt} = credit_{ijt}/\sum_j credit_{ijt}$ where $credit_{ijt}$ is the total amount of credit granted by bank j to firm i in year t. And we define $line_{ijt} = credit\ line_{ijt}/credit_{ijt}$, where $credit$ $line$ is the amount of the credit line.

Our identification assumption is that, after controlling for all these variables, any remaining unobserved determinant of the *composition of changes* in credit granted to the same firm by different banks is uncorrelated with the variable of interest, $Z_{it} * LowCap_{jt}$.

4.2   Basic results

The results of estimating equation (1) are reported in Table 1. In column (1) we report a specification with separate year and firm fixed effects. The estimated coefficient on *LowCap* is negative but not statistically significant, but its interaction with *Zombie* is positive and significant at the 1% level. Thus, banks with a capital ratio below the median extend relatively more credit to weak firms than to healthy firms, compared to banks with more capital. Note that the sum of these two coefficients is not significantly different from 0 (the p-value is in the last row of Table 1). Thus, bank capital influences the composition of credit growth in terms of firm quality, but not the overall amount of credit extended to zombie firms. The estimated coefficient of 1.5 on the interaction $Z * LowCap$ means that a bank with low capital allows credit to zombies to grow faster than credit to healthy firms by 1.5%. Recall that bank credit was shrinking throughout this period, by -8% per year on average. Thus, the estimated coefficient of 1.5 corresponds to almost 20% lower credit reduction to zombies vs healthy firms if the bank has low capital. Also, well capitalized banks cut credit growth to zombie firms, relative to healthy firms, by about 5.6%.

Column (2) adds the firm-year fixed affects, that accounts for unobserved heterogeneity at the firm level. The interaction coefficient drops slightly and remains significant, but now the estimated coefficient on *LowCap* becomes more negative and significant at the 5% level. The point estimate implies that low-capital banks cut growth to healthy firms by about 1.6%, relative to well capitalized banks. This corresponds to about 20% of the average credit contraction during this period, a large effect. The sum of the two

15

coefficients of interest remains insignificantly different from zero, implying that the only effect of low bank capital is to reduce credit growth for healthy firms, with no impact on credit to zombies.[5]

In column (3) we add two variables that account for pre-existing bank-firm relationships, namely the share of the bank in total firm's credit and the composition of loans across different credit facilities. Credit growth is negatively related to the share of credit that a bank extends to a firm and positively related to the share extended through credit lines. But the coefficients of interest are not materially affected or rise in absolute value.

In column (4) we introduce bank fixed effects and some time-varying bank controls, namely the *liquidity ratio* (the ratio of cash and government bonds to total assets), the *interbank ratio* (the ratio of interbank deposits and repos with banks–excluding those with central banks–and total assets) and *ROA* (the ratio of bank profits to bank total assets). These indicators are meant to capture other bank characteristics that might influence lending policies and possibly correlated with the capital ratio. They do influence credit growth, without however affecting our coefficient of interest.

Finally, in columns (5) and (6) we disaggregate credit granted according to whether it is collateralized or not. Loss provisions on non-performing loans are substantially smaller if credit is guaranteed by collateral. Thus, the bank has much stronger incentives to hide losses for non-collateralized loans. Column (5) displays the same regression as in column (4), but the dependent variable is the growth of credit covered by some collateral. In column (6), the share of coallateralized loans is zero. The two coefficients of interest are statistically different from zero (and with the same pattern as in column 4 although larger in absolute value) only on non-collateralized loans.

Overall, Table 1 implies that the main difference between low vs high capital banks concerns credit extended to healthy firms. Low-capital banks cut credit more aggressively to healthy firms than to zombie firms. This results in significantly lower credit growth for healthy firms who borrow from a low-capital bank, relative to a high capital bank, while zombie firms are not significantly affected by bank capital. These effects are large, and correspond to about 20% of average credit contraction during the period.

4.3 Other predictions

Next, we consider the other predictions about the effects of low capital on bank lending behavior.

---

[5]When we include firm-year effects, the zombie dummy is absorbed by the firm-year fixed effects, and we can only estimate the relative effect of low vs high capital banks on each firm type.

Extensive margin   So far, we have focused on the intensive margin, that is, changes in the amount of credit granted, conditional on the continuation of the credit relationship. But credit can also be reduced by shutting down a credit relationship, something not captured by our credit growth indicator. We thus also explore the extensive margin through a survival analysis of the credit relationship.

In Table 2 we re-estimate the same specifications as in columns (1-4) of Table 1, except that the dependent variable is a dummy variable that equals 100 in the year in which the relationship is terminated, and 0 in previous years (the value of 100 is chosen so that the coefficients can be interpreted as percentage points).[6] In all columns, only the interaction coefficient β_2 is statistically significant and has a negative value, as expected (i.e. low-capital banks are less likely to terminate a relationship with zombies than with healthy firms, compared to high-capital banks). Unlike in Table 1, however, here the sum of the estimated coefficient of interests, on $LowCap$ and on $Z*LowCap$, is negative and statistically significant at the 5% level or lower in all columns except the first one. Thus, low bank capital here makes it more likely that a relationship with zombie firms survives, while it has no effect on the survival of relationships with healthy firms. With reference to column (4), the sum of the two coefficients of interest is almost -1, meaning that on average the probability that a credit relationship with a zombie firm survives for one more year is 1 percentage point larger if bank capital is below the median, than if it is above the median. This is a large effect, considering that on average 5.6% of all relationships are terminated every year.

Non-performing loans.   Next, we study how bank capital affects the decision of a bank to classify loans as non-performing. There are different classes of non-performing loans, involving different degrees of discretion by banks. The first class is "past-due". If a repayment of a loan is late by more than 180 days, the bank has to classify the loan as past-due. Banks may avoid this by providing a new loan to the borrower or by restructuring the existing one, for example by replacing the original loan with a new one with longer maturity. Otherwise, a past-due involves little discretion by the bank. The other two categories are "substandard loans" and "bad loans"; both involve a subjective evaluation by banks. A loan can be classified as substandard when the firm is "facing temporary difficulties - defined on the basis of objective factors - that are expected to be overcome within a reasonable period of time". This entails a degree of discretion in credit evaluation, which is a natural part of the activities performed by banks. Bad loans are those for which banks expect to recover only a small fraction of the nominal value. The

---

[6]Given the very large number of fixed effects, we cannot estimate logit or probit models, so that we run linear probability models (OLS).

decision to classify a loan as bad is to some extent arbitrary, as banks must come to the conclusion that a borrower is not able to repay and classify the loan as a defaulted loan.

Classifying a loan as substandard or bad has two consequences. First, it forces the bank to set aside a provision for future losses, thus reducing current profits. Banks with a weak capital structure may be reluctant to do this. Second, a bad loan classification has a very negative effect on the firm's access to credit. The classification is reported to the Centrale dei Rischi and all banks are notified of the event. As a result, the firm is basically excluded from the loan market. Therefore, if a bank wants to keep a zombie alive, it will refrain from classifying its loans as substandard or bad. For both reasons, we expect that under-capitalized banks are less likely to do so.

To test this hypothesis, we run a set of regressions in which the dependent variable is a dummy variable equal to 100 (again, to easy interpretation) if a loan is classified as non-performing between t and $t+1$. We construct a dummy variable for the three different types of procedures: bad loans, sub-standard loans and past due. Throughout, we only display the more comprehensive specification corresponding to column (4) in the previous two tables. Note that this is a demanding test, for two reasons. First, our firm-year fixed effects specification identifies the estimated coefficient from differences in the bad loan classification across banks. Only about 4.7% of all bad loans in our sample are not classified as such by all banks.[7] Second, the benefit for a bank of delaying a substandard or bad loan classification may not be long lasting, as supervisors may require banks to do so anyway, or they may impose writedowns in order to increase coverage ratios, i.e. the ratio between write-downs and the overall stock of non-performing exposures.[8].

With these caveats in mind, we show results in Table 3. For the classification into bad and substandard loans (columns 1 and 2 respectively), the interaction coefficient β_1 is negative and significant. Thus, low capital makes a bank less likely to classify a loan as bad or substandard if it involves a zombie firm rather than a healthy firm. The estimated coefficient on $LowCap$ is not statistically significant at the 5% level, and the sum of the two coefficients is negative and significant. Thus, having low bank capital reduces the probability that a zombie loan is classified as bad or substandard, and has no effect on loans with healthy firms. The point estimate of about -0.5 means that having low bank capital reduces the probability of these classification by about -1/2 percentage point if the loan is with a zombie firm. Every year about 1.5% of loans are classified as bad.

---

[7]For this paper we are using yearly data from the Credit Register. It is possible that a bank classifies a borrower as a bad loan, say in June and the other banks follow, say, in September, so that as of December, the borrower has been classified as a bad loan by all banks.

[8]In 2012 and 2013 the Italian supervisor conducted targeted inspections on 20 major banks with the aim of verifying credit risk and increase coverage ratios. This resulted in banks increasing writedowns by 50%

Hence, having low bank capital reduces such classifications by about one third if the firm is a zombie, a very large effect. Recall that our estimates include firm-year effects. This rules out assortative matching of firms to banks or specific shocks to firm credit demand. Rather, we are comparing the decisions of different banks over the same firm, as we are only using within firm-year, across banks variability to identify the parameters.

The last column considers classifications of loans into past-due. Here, the estimate of the interaction coefficient β_1 is positive and significant (while the estimated coefficient on $LowCap$ is almost 0). Thus, loans from zombie firms are more likely to be classified as past due if they originate from a low capital bank. On the one hand, this reflects the very low degree of arbitrariness in turning these flags on. On the other, it might be that firms strategically decides to delay payments to weak banks, being aware that these are less likely to turn on a substandard or bad loan flag. This interpretation is consistent with Schiantarelli et al. (2016), who show that firms strategically decide to pay late more often when borrowing from a weak bank, because such banks are more likely to tolerate delayed payments.

Interest rates   If the main driver of zombie lending is to hide losses, then we expect interest rates on the loan to be low. Subsidized credit is extended in order to keep the firm solvent, and raising interest rates could create difficulties for the borrower or attract the attention of regulators. If on the other hand a low-capital bank was gambling for resurrection, then the oppsite should be observed: the bank charges very high interest rates on risky loans, knowing that limited liability shields its shareholders from the downside risk. To discriminate between these two hypotheses, column (4) of Table 3 reports the usual most comprehensive specification, but now the dependent variable is the interest rate charged on the loan (results are similar for the more parsimonious specifications). The estimated coefficients on $LowCap$ and its interaction with Z are not statistically significant and close to 0. Thus, this evidence too is consistent with the motive of hiding losses, and not with the idea that under-capitalized banks gamble for resurrection.

Evergreening

The incentive of a bank to roll over credit to a weak firm is stronger if it accounts for a large share of the firm's total debt. The reason is that in such a case, if the loan is not rolled over, the firm is more likely to default on its debt service obligation. Hence, we should observe zombie lending particularly when the bank is one of the main creditors of the firm. To test this hypothesis, we extend the specifications in Table 1 by adding all the interactions of $LowCap$ and Z with the variable $Share\ bank$ defined above. The dependent variable is yearly credit growth, as in Table 1. The results are displayed in columns (5)-(6) of Table 3 for the two specifications corresponding to columns (3) and (4)

of Table 1. The estimated coefficient on the interaction $Share\ bank * Z$ is positive and signficant, while that on the triple interaction $Share\ bank * Z * LowCap$ is not statistically different from zero. Thus, as the share of the bank in the firm's total credit increases, all banks (and not just those with capital below the median) are more likely to roll over the credit if the firm is a zombie than if it is healthy. In other words, evergreening of zombie firms is not confined to banks with capital below the median. This can be understood by recalling that during this crisis period all Italian banks where under strong pressure to boost their capital. Finally, the estimated coefficient on $LowCap * Z$ continues to be positive and statistically significant, and not much different from that in Table 1, confirming our previous finding that banks with low capital are more likely to cut credit growth if the firm is healthy than if it is a zombie, compared to better capitalized banks.

Summary   All in all, this evidence is consistent with the hypothesis that low bank capital induces banks to cut credit to healthy firms rather than to zombies, because low-capital banks try to hide losses and delay the moment in which they will be required to raise new capital. Whether or not this behavior actually results in more lending to zombie firms by weaker banks, depends on the credit growth indicator. There is evidence that this happens at the extensive margin, where weaker banks are less likely to terminate a relationship with a zombie firm, compared to stronger banks. On the intensive margin, on the other hand, a reduction in bank capital hurts the healthy firms without however benefiting the zombie firms. Finally, and consistently with our interpretation, banks with low capital are less likely to recognize a loan as substandard or bad if it is with a zombie rather than a healthy firm, compared to more capitalized banks. But there is no evidence that the terms of the loan are affected by bank capital and by the viability of the firm.

4.4   Robustness

Here we study the robustness of our results to various modifications of the basic setting. To save on space, unless otherwise noted we only report regressions based on the most comprehensive specification that always includes firm-year and bank fixed effects plus the time varying bank controls and the variables $Share\ bank$ and $share\ credit\ line$ defined above (i.e. column 4 of Table 1). Results are displayed in the Appendix.

Definition of zombies.   One key issue relates to the definition of zombie firms. In Appendix Table A3 we repeat the estimations using alternative definitions of zombie firms, namely $Zombie\ 2$ and $Zombie\ 3$ in columns (1) and (2) respectively. As seen in Section 3, $Zombie\ 2$ is a more restrictive definition of zombies. For example, in the crisis years 11% of firms are classified as zombies according to this definition, against 19% of the

previous one. Notwithstanding this difference, the results are similar to those obtained with the basic definition of zombies, except that now the estimated coefficient β_1 is even larger.

Another issue is the binary nature of our zombies indicators, that classify as zombies firms that pass the established thresholds of profitability and leverage. Given the possible arbitrariness of the thresholds defining the zombies, columns (3)-(4) of Appendix Table A3 replace the variable *Zombie2* with the continuous indicators measured by the corresponding principal components (see above) Higher values of $PC1$ and $PC2$ correspond to weaker firms. Again, we find that the estimated coefficient on *LowCap* is negative and signficant, while the interaction coefficient is psositive and signficant. Thus, low bank capital leads to lower credit growth, but this effect is dampened for weaker firms. To give a sense of the magnitude, consider two firms with a difference in the value of *PC EBITDA/INT leverage* of one standard deviation (about 1). Using the estimate of 1.03 in column (4), a reduction in bank capital from above to below the median implies a faster credit growth to the weaker firm (compared to the stronger one) of 1 percentage point. Results are similar when we use the other principal component, *PC ROA leverage* (columns 3 and 4).

Definition of bank capital structure. Next we experiment with alternative definitions of bank under-capitalization. Above we defined a bank with low capital if its capital ratio is below the sample median in 2008 (about 11%). We experiment with other thresholds to check the sensitivity of the results to this choice. In column (1) of Appendix Table A4, we redefine the threshold for having low capital as being below the median year by year (rather than in 2008). Results are qualitatively similar to the baseline, but both coefficients of interest are larger in absolute value.

Column (2) replaces the *LowCap* dummy with a continuous capital ratio indicator (thus higher values correspond to more capital). The estimated coefficient is positive and significant, while the interaction with Z is negative and signficant, as expected. The numerical value of -0.39 on the interaction implies that an increase of one standard deviation in the capital ratio (2.4%) would imply a reduction in credit growth to zombie relative to healthy firms of almost 1 percentage point.

Figure 5 shows that banks closer to the regulatory threshold are more likely to lend to zombies. To test if the intensity of the effect changes with a more stringent definition of weak bank, we construct a dummy variable equal to 1 if the bank capital ratio is below 9 (*Dcapratio < 9*), a value below which bank capitalization is particularly at risk. Banks in this danger zone are small: about 20% of all banks in our sample had a capital ratio below 9% in at least one year, but they only account for about 5.3% of all the bank-firm

21

relationships in our sample, and the dummy variable is one for only 4% of observations. These banks do not behave signficantly different from others with regard to healthy firms (the estimated coefficient on the dummy variable $Dcapratio < 9$ is negative but not significantly different from zero), but its interaction coefficient with Z is highly significant and large. The point estimate of 3.3 implies that the difference in credit growth between zombie and healthy firms was over 3 percentage points higher if the bank capital ratio fell below 9. This confirms that the effects of capital requirements on lending policies are likely to be non linear, and stronger closer to the regulatory threshold.

The remaining columns of Appendix Table A4 explore the effects of three other indicators of bank weakness in columns (4), (5) and (6) respectively: a dummy variable if the bank return on assets is below the median (roa), the leverage ratio, (*high bank leverage*) and a dummy variables if bad loans are above the median (*high bad loans*). Only the *high bad loans* dummy variable has a positive estimated coefficient when interacted with Z. Leverage is never statistically signficant, on its own or interacted, and banks with low return on assets lend more to healthy firms, compared to banks with higher roa, but there is no difference in their lending to zombie vs healthy firms. Thus, only regulatory indicators of bank strength predict a differential growth of credit to zombie vs healthy firms, while market oriented measures of bank strength such as roa or leverage do not. This too is consistent with our hypothesis that zombie lending by weak banks in this period reflects an attempt to hide losses from regulators, to avoid or delay requests to boost capital.

Finally, we also estimated similar regressions in the pre-crisis period, 2003-2007. We did not find any evidence that banks with low capital extended more credit to zombie firms than to healthy firms, compared to stronger banks (results not reported). Regulatory capital only mattered for credit growth during the crisis period, when both regulators and markets started paying much more attention to bank capital. This finding can be thought as a placebo test, that further reinforces our interpretation.

Table 4 combines the intensive and extensive margins by computing the growth of total credit granted at the level of the firm, aggregating across banks.[9] For each firm, we compute the share of low capitalized banks out of all banks from which a firm borrows, using the share of credit from each bank as weights. We find that healthy firms record a lower growth in credit granted the larger the share of low capitalized banks they borrow from. According to the estimates of the most saturated regression in column (4), a firm borrowing only from low capitalized banks would record a drop in the growth of credit of 1.5% compare to a firm borrowing from high capital banks only. The effect is opposite and

---

[9]Compared to the basic regressions of Table 1, here an observation is a firm-year, so that we cannot include firm-year effects anymore. As such, these regressions might capture both credit demand and supply effects and should therefore interpreted with care.

large for zombies: the same exercise delivers an increase in the growth of credit of about 2.4%, highly statistically significant. Overall, this suggests that banks' capitalization has substantial effects on the allocation of credit across firms.

5 The economic consequences of zombie lending

In the previous sections we have shown that, during the crisis, weak banks were more reluctant to cut credit to very weak firms and to terminate a credit relationship, in general and with zombie firms in particular. The magnitude of this effect of low bank capital is economically relevant: 2 percentage points of additional yearly credit growth going to zombie firms if bank capital is below the median, corresponding to a 25% increase relative to the average yearly contraction of credit of -8% during the crisis. We now ask how this phenomenon affected real economic activity. Since we found an effect of bank capital on zombie lending only during the crisis years, throughout this analysis we restrict the sample to the period 2008-2013.

We break the question in three parts. First, following Caballero et al. (2008), we study the effects of zombie lending on the growth of healthy firms. Prior research based on different episodes or different samples has concluded that lending to unprofitable firms hurts their healthy competitors, slowing down their rate of growth (Caballero et al. 2008, Acharya et al. 2016). This is because the supply of bank credit available to healthy firms is reduced, and also because the subsidy received by zombies distorts competition in the product and input markets. During a sharp recession, however, this negative effect on healthy firms could be mitigated by the positive aggregate demand externalities of reducing firm bankruptcies (Mian et al. 2015). In the next subsection we explore which of these effects prevails in our sample. Second, zombie lending affects the composition of bankruptcies: more zombies are kept alive, and possibly more healthy firms are pushed into bankruptcy. We explore this issue in Subsection 5.2. Third, building on the insight of the literature on misallocation (Hsieh & Klenow 2009), we consider the implications of zombie lending for the dispersion of productivity across firms. In a frictionless economy, factors of production would be allocated to firms so that the marginal value product of inputs – and thus revenue productivity – is equalized across firms. Zombie lending reduces the efficiency of the allocative process, both because inefficient firms are kept alive (or prevented from shrinking), and because healthy firms find it more difficult to grow. As a consequence, zombie lending should increase the dispersion of productivity across firms. We address this implication in Subsection 5.3.

A key issue is how to define the group of firms within which these effects take place. Caballero et al. (2008) study Japanese listed firms only, for which the relevant markets

are national (or even international). Accordingly, they use the sector as the reference group. Acharya et al. (2016) follow this approach and, given that they have a sample of firms from different European countries, they use the country-sector. Our sample instead consists of all incorporated firms, including very small firms. For this reason, we also consider geography. Many firms in our sample have access only to the local lending market. Since banks tend to be geographically specialized, and often competing firms are also geographically concentrated, we aggregate zombie lending at the province-sector level. Provinces are administrative units roughly comparable to a US county. As argued by Guiso et al. (2013), they constitute an ideal geographical unit to define the credit market: in fact, according to the Italian Antitrust authority, the "relevant market" in banking for antitrust purposes is the province. Moreover, provinces are also a natural boundary to define a local labor market, within which firms compete for workers.[10] In terms of sector, we exclude agriculture and finance and divide the other firms in 18 sectors.[11]

5.1 Firm growth

How does zombie lending affect different growth indicators of individual firms operating in the same province-sector? This is the question addressed in this subsection.

5.1.1 Identification

The typical framework used in the literature to assess the effects of zombie lending on non zombie firms entails to regress firms performance on the incidence of zombies:

$$\Delta y_{ipt} = \beta_0 + \beta_1 ShZ_{pt} + \beta_2 Z_{ipt} * ShZ_{pt} + \beta_3 Z_{ipt} + Dummies_{ipt} + \eta_{ipt} \qquad (2)$$

where i denotes the firm, p the area-sector, and t the year. The dependent variable Δy_{ipt} is a measure of firm performance, such as the growth rate of inputs or output and ShZ_{pt} is the share of zombies in area-sector p at t. The coefficient β_1 captures the effect of ShZ_{ipt} on the performance of healthy firms, while β_2 that of ShZ_{pt} on zombies, *in deviation from that on zombies*.[12] The hypothesis that zombies hurt non zombies is formalized as

---

[10]The national institute for statistics define local labor markets using census data on workers' commuting patterns. It turns out that local labor markets so defined are smaller than provinces. However, for our study the most relevant market is the banking one, so that we decided to keep the province as our preferred geographical unit.

[11]Specifically, the sectoral classification is: Food and tobacco; Textile and leather; Wood; Paper; Chemicals; Minerals; Metals; Machinery; Vehicles, Manufacturing n.e.c.; Electricity gas, water; Constructions; Wholesale and retail trade; Hotels and restaurants; Transport, storage, communication; Real estate, renting and business activities; Professional, scientific and technical services; Business services.

[12] The previous literature typically uses a different parametrization, that is, $\tilde{\beta}_1 ShZ_{pt} + \tilde{\beta}_2(1 - Z_{ipt}) * ShZ_{pt}$, using zombies as the reference group and estimating the relative effects on non-zombies. We use the parametrization in equation 2 for symmetry with the analysis of the previous section. Of course, the two parametrizations deliver identical results, as $\beta_1 = \tilde{\beta}_1 + \tilde{\beta}_2$ and $\beta_2 = -\tilde{\beta}_2$.

$\beta_2 > 0$. In particular, when the dependent variable measures the growth rate of inputs, the coefficient β_2 captures both the crowding out channel and the implicit subsidy channel discussed above. Both channels reinforce each other and slow down input growth. When the dependent variable measures the growth of output, instead, the coefficient β_2 mainly reflects the implicit subsidy channel, hence its expected sign is still negative.

The key identification problem in estimating (2) is that the share of zombies is correlated with shocks affecting the performance of both zombies and non zombies, such as demand shocks. An adverse demand shock in area-sector p is bound to increase the share of zombies and also negatively affect the performance of firms operating in the same area-sector. This problem is well understood by the literature and is addressed by focusing on the *relative* performance of non zombies vs zombies, captured by $-\beta_2$. In particular, Caballero et al. (2008), Acharya et al. (2016) and McGowan et al. (2017) specify the vector of dummy variables as a full set of country-sector-year dummies (in our setting this is a set of province-sector-year dummies). In this regression, the area-sector-year dummies perfectly control for any aggregate shock. The coefficient β_1 is not identified, however, because the variable ShZ_{pt} is absorbed by the dummies. So the regression estimates β_2 as the effect of more zombies on the relative performance of zombies and non zombies. This coefficient should capture the implicit subsidy and the crowding out effects. Note that β_2 cannot capture aggregate demand externalities, since these are likely to affect both non-zombies and zombies.

The literature neglects a second identification problem with this approach, however, due to firm heterogeneity. This problem is illustrated in Figure 6, where the lighter curve depicts an hypothetical distribution of firms in an area-sector. The horizontal axis is a measure of firm "quality", such as growth prospects. Zombie firms are those below a given threshold, T_Z in the Figure. Healthy firms are those to the right of T_Z. We are interested in the difference between the average performance of healthy vs. zombie firms, namely $\mu^{NZ} - \mu^Z \equiv .\beta_2$, where $\mu^{NZ} \equiv E(x|x > T_Z)$ and $\mu_s^Z \equiv E(x|x \leq T_Z)$ denote the mean of healthy and zombie firms respectively. In particular, we want to know how random changes in ShZ_{pt}, the share of zombies in area-sector p at t, affect $\mu^{NZ} - \mu^Z$ through the spillover effects described above (distortions of competition and lower credit supply to healthy firms). According to the prevalent interpretation in the literature, this can be assessed by the estimate of $-\beta_2$ in equation (2).

The implicit identifying assumption behind this approach is that, in the absence of spillover effects, shocks that change the share of zombies have the same effect on the performance of zombies and healthy firms, that is, they do not affect $\mu^{NZ} - \mu^Z$. Unfortunately, this assumption is unlikely to hold in the data and, therefore, β_2 cannot identify the effects of zombies on non zombies even if one includes area-sector-year dummy variables in equa-

tion (2). To see this, suppose that the area-sector is hit by a negative shock that shifts the whole distribution of firms to the left, to the darker curve depicted in Figure 6. Three things happen. First, the share of zombie firms, ShZ_{pt}, increases (the area to the left of T_Z rises, as illustrated by the shaded area in Figure 6). Second, both conditional means μ^{NZ} and μ^Z change, and presumably drop.[13] This is the standard identification problem discussed above, addressed in the literature by the inclusion of area-sector-year dummy variables. Third, the difference between the conditional means, $\mu^{NZ} - \mu^Z$, could also be affected, in a manner that depends on the shape of the distribution. This identification problem is neglected in the literature, but it is relevant for a large class of distributions.

Specifically, in the appendix we show that, under a simple condition on the distribution of performance, a shift to the left in the distribution induces a drop in the difference $\mu^{NZ} - \mu^Z$. We illustrate this with a numerical simulation. Consider the case of the normal distribution with unit variance and mean equal to 5 (the choice of the mean is inconsequential for the results). Assume that a firm is classified as zombie if its quality is below 3. We perform the following experiment. We generate negative shocks $s = 0.01, 0.02, ..., 3$ that progressively shift the distribution to the left, $\mu(s) = 5 - s$, and compute $\mu^{NZ}(s) - \mu^Z(s)$, that is, the difference in the average quality of non zombies and zombies, for each value of s. Panel A of figure 7 plots this difference and shows that it is decreasing for $s < 2$, that is, as long as the zombie threshold is to the left of the mean of the distribution (for $s = 2, \mu(s) = 3$, equal to the zombie threshold). Panel B of the figure plots $\mu^{NZ}(s) - \mu^Z(s)$ against the share of zombies (the latter obviously increases with s). Here too we find a negative relationship, as long as the share of zombies is below 50%. This condition is generally met in the papers on zombie lending. For example, in Acharya et al. (2016) the share of zombies varies between 3% in Germany and 20% in Italy, while in Caballero et al. (2008) it varies between sector and over time, but it exceeds 20% only in a few years in Services and Real Estate (see their Figure 3). In our case, we classify as zombies 19% of firms during the crisis years. Thus, in this very standard setting and without any negative spillovers occurring from zombies to non zombies, the estimation of equation 2 would deliver a positive coefficient β_2, corresponding to a negative relative performance of healthy firms. But this simply reflects a property of the distribution of firms, and has nothing to do with the hypothesis that a larger share of zombies hurts healthy firms through spillovers in credit, product or input markets.[14]

---

[13]Note that, for some distributions, a leftward shift might actually increase μ^{NZ}, the conditional mean above the threshold. However the mean surely decreases for log-concave distributions (Barlow & Proschan 1975), a family that includes many commonly used distributions, such as the normal, the Laplace and the logistic.

[14]Note that in our simulation we are likely to underestimate the extent to which $\mu^{NZ}(s) - \mu^Z(s)$ decreases with s. The reason is that very low quality firms could exit the market. This would limit the

To cope with this problem, we need a variable that moves the shares of zombies in a province-sector-year but that is orthogonal to local-sectoral shocks. In what follows we use a measure of under capitalization of the banks that lend in the province-sector. As a measure of banks weakness, we construct the credit-weighted average value of the variable $LowCap_{pt}$ used in the previous section:

$$\overline{LowCap}_{pt} = \frac{\sum_j LowCap_{jt} * Credit_{jpt}}{\sum_j Credit_{jpt}} \tag{3}$$

where $Credit_{jpt}$ is the amount of credit granted by bank j to province-sector p in year t. Thus, $\overline{LowCap}_{pt}$ is the share of loans granted in each province-sector-year that originate from banks with a capital ratio below the median. We have shown in Section 4 that this indicator captures zombie lending. We expect that, in sector-province where banks are weaker, the tendency to engage in zombie lending hurts healthy firms through the two channels described above. But these spillover effects could be mitigated by reduced adverse aggregate demand externalities, if zombie lending also reduces bankruptcies and layoffs.

While endogeneity concerns are first order when using the share of zombies in equation (2), they are much less likely to be a problem with $\overline{LowCap}$. The exclusion restriction is that bank capital is exogenous with respect to the conditions prevailing in a province-sector-year: that is, it is orthogonal to shifts of the distribution. The banks in our sample are typically active in several province-sectors, so that capital shortages are not due to adverse conditions in one particular province-sector-year. Indeed, on average banks are active in about 48% of sector-provinces (the median is very similar). Moreover, the 95-th percentile of the distribution of the share of of lending is 1.39%. The share reaches 6.46% only at the 99-th percentile. The distribution is therefore extremely skewed towards zero, the lower bound. Shares of banks' loan portfolio above 5% are concentrated in a handful of sectors, such as construction and wholesale and retail trade, characterized by the presence of some very large firms, and in the provinces in which these large firms have their headquarter (the great majority of these are in Milan, Rome and Turin, the largest cities in the country). Large concentrations of a banks' portfolio also occur in the case of small banks whose operations are geographically concentrated. For banks with assets valued more than 50 billion euros, the share of the loan portfolio is above 5% in only 55 province-sector-year cells (out of 18,809 year-sector-province cells). As a further

---

drop in performance of (surviving) zombies (and hence the drop in $\mu^Z(s)$) when shocks hit. This can be seen again in Figure 6, where we also added an exit threshold T_D. When we shift the distribution to the left, the drop in the average quality of zombies is reduced by the fact that extremely low quality zombies drop out of the market. At the same time, as long as the density is higher at the zombie threshold T_Z than at the exit threshold T_D, we still obtain that a leftward shift in the distribution increases the mass of zombies.

robustness check, we also run our tests excluding province-sector-year cells in which at least one bank has a share of its loan portfolio above 5%, as well as the whole province-sector in which at least one bank has a share of its loan portfolio above 5% in any year. Although the number of observations drops substantially in the two exercises, the results are very similar to those based on the whole sample. We therefore maintain that bank capital is exogenous with respect to the conditions prevailing in a province-sector-year; in terms of Figure 6, it is orthogonal to shifts of the distribution.

An additional endogeneity concern is that the shares of credit might be correlated with local-sectoral shocks. For example, when a negative shock hits a province-sector, low-capital banks might expand their credit shares. To account for this possibility, we also construct an alternative measure of banks weakness based on the share of loans in the pre-crisis period. Specifically, we compute

$$\widehat{LowCap}_{pt} = \frac{\sum_j LowCap_{jt} * Credit_{jp04-07}}{\sum_j Credit_{jp04-07}}, \tag{4}$$

where $Credit_{jp04-07}$ is the total credit that bank j extended to province-sector p in the period 2004-2007. For this variable, credit shares are fixed at their pre-crisis average values, so that they are by construction exogenous with respect to shocks that occur during the crisis. In what follows, we use $\overline{LowCap}_{pt}$ as our main variable, as it represents a more accurate description of the credit condition at the sectoral-local level during the crisis. It turns out that the shares are fairly stable: the correlation between $\widehat{LowCap}_{pt}$ and $\overline{LowCap}_{pt}$ is 0.83. To make sure that the potential endogeneity of credit shares is not driving our conclusions, in the appendix we report the tables that replicate all the regressions using $\widehat{LowCap}_{pt}$ instead of $\overline{LowCap}_{pt}$ as regressor. We find very similar results.

We again use Figure 6 to illustrate the possible effects of $\overline{LowCap}$ on firms performance. Consider first zombie firms. We have seen that weak banks provide more credit to them. This can have two effects. On one hand, it keeps very low quality zombies alive: the failure threshold T_D in Figure 6 shifts to the left. This implies that the performance of zombies should deteriorate (extensive margin effect: weaker selection). On the other hand, with more credit, zombies can expand operations (or contract less): the intensive margin effect implies that their performance improves. Which effect dominates is an empirical question.

Next consider healthy firms. First, their performance can be negatively affected by bank weakness, because of the spillover effects induced by zombie lending (implicit subsidy to inefficient competitors and reduced credit availability). Second, in the opposite direction, zombie lending could mitigate the adverse aggregate demand externalities, through reduced layoffs and bankruptcies. Third, there might be a negative direct effect of $\overline{LowCap}$

28

on healthy firms, if low capitalized banks supply less credit independently from the presence of zombies. So any effect we find is an upper bound to the pure zombie channel. Note that this is not necessarily a limit of our analysis: we estimate the total effect of banks low capitalization on the growth performance of healthy firms, rather than the partial effect going through the zombie lending channel. From a policy perspective, the total effect is as important, if not more important, than the partial one.

Finally, it is important to stress the difference between the relative effect of $\overline{LowCap}_{pt}$ on healthy firms with respect to zombies, β_1, and the absolute one, measured by $\beta_1 + \beta_2$. We have seen that $\overline{LowCap}_{pt}$ is likely to affect the performance of zombies. In this case, β_2 identifies the differential effects on zombies, but in itself it is not enough to assess the total effect. For example, it might be that the performance of zombies improves and that of non zombies is unaffected: in this case, the relative effect would be negative but the total effect would be zero. Our approach has an important advantage over the previous literature. Because the variable $\overline{LowCap}_{pt}$ is unlikely to be correlated with shocks at the sector-province level, we can also estimate equation (2) without including province-sector-year dummies and still obtain consistent estimates of of β_1 and β_2 and hence of the total effect $\beta_1 + \beta_2$.

5.1.2 Results

As a first exercise, we have replicated the regressions run by the previous literature of firm performance on the share of zombies at the province-sector-year levels. We find results in line with the previous literature. Table A7 report firm-level regressions of employment growth (measured by the growth rate of the wage bill), of capital growth and of sales growth on the share of zombie firms at the province-sector-year level, by itself and interacted with a dummy for zombie firms. In odd columns we control for province-sector and year fixed effects, so we can estimate both β_1 and β_2 in equation (2). We find all performance measures deteriorate more for non zombie firms than for zombies as the share of zombies increases. This result survives the inclusion of a full set of province–sector-year dummies (even columns), in which case we can only identify the relative effects between zombies and non zombies. As the previous literature, we also find that the relative performance of non zombies gets worse as the share of zombies increases.

Despite the substantial differences in the settings, particularly in terms of firms included in the exercise (listed firms for the other papers, all firms in our case) and definition of reference group (country-sector-year vs. province-sector-year), the magnitudes are also comparable, particularly with Caballero et al. (2008). They find a $\tilde{\beta}_1$ of -0.0454, very

similar to $\beta_1 + \beta_2$,[15] and a β_2 of -0.0232 (-0.0188 in the specification with sector-year fixed effects), smaller than our estimates of around -0.06. This might be due to the much finer geographical definition of our analysis. [16]. The results in Columns 1 and 2 of Table 5 are clear cut: the negative relationship between the share of zombies and the relative performance of non zombies is a very robust empirical finding also in our setting. Unfortunately, given our discussion above, it is likely to be a mechanical consequence of the leftward shift in the distribution and cannot in itself be interpreted as evidence of negative spillovers from zombies to non zombies.

We next move on to estimating our preferred regression, where ShZ is replaced by $\overline{LowCap}$. As argued above, our credit supply indicator is less subject to the endogeneity issue compared to ShZ_{pt}, because the banks' capital ratio is unlikely to be affected by shocks at the province-sector level. Table 5 reports the results. For labor,, we find no effect of bank capitalization on healthy firms: the coefficient β_1 is small and statistically insignificant. The coefficient β_2 is instead positive and highly significant: under-capitalized banks increase labor expansion of zombie firms relative to healthy firms. Using the estimated coefficient of 0.038 on $\overline{LowCap}_{pt} * Z_{ipt}$ in column (1), increasing the capitalization of the weak banks so that they are all above the threshold used to define a weak bank (i.e. so that $\overline{LowCap}_{pt} = 0$) would imply that zombie firms would decrease the growth of their wage bill by 1.6% *relative to zombies*. Given that the coefficient of healthy firms is basically zero, these relative effects can be also directly interpreted in absolute terms.

To assess if our estimates are robust to the presence of local-sectoral shocks, Column (2) estimates a specification that also includes province-sector-year dummy variables. The estimate of β_2 is unaffected, suggesting that local shocks are not a major concern. Of course, we cannot infer anything about the size of the absolute effect, since $\overline{LowCap}_{pt}$ on its own is absorbed by the dummy and β_1 cannot be estimated.

The remaining columns of Table 5 repeat the same exercise for the other measures of firm performance, For capital, we find that neither β_1, nor β_2 or their sum are significantly different from zero: banks' capitalization does not affect capital accumulation. For sales, we find effects that are similar to those for labor, although the relative effect is somehow smaller in absolute value. A possible interpretation of this results is that zombie firms use the extra credit they obtain from weak banks to pay for working capital to stay afloat,

---

[15]See footnote 12 for an explanation of the relationship between their parametrization an ours.

[16]Comparisons with Acharya et al. (2016) are less straightforward. In fact, they further split non-zombies into high and low quality firms and include firm fixed effects. They find no relative effect for low quality healthy firms, while a very large coefficient, of -0.5, for high quality healthy firms. But introducing a second threshold that distinguishes low and high quality healthy firms further exacerbates the identification problems in interpreting the relative coefficient (see our previous discussion of Figure 6). Results are available upon request.

rather than for investments. When denied credit, they need to cut employment and production, while when they receive it they use it to pay workers and suppliers (regressions of intermediates expenditure confirm this hypothesis). Healthy firms performance is not affected by banks capitalization because on one side they have enough cash flow to cover their working capital, on the other given the very negative cyclical condition they cut investment and therefore the corresponding credit demand.

We have performed several robustness checks. First, we have experimented with different set of dummy variables. Our preferred specification controls for sector-province and year fixed effects. We have also experimented with sector-year and province-year fixed effects. In general, we confirm the overall results, with the only noticeable difference that, for employment growth, when we increase the set of dummies we find some evidence of a negative absolute effect on non-zombies. Second, we have run a different specification. As argued above, $\overline{LowCap}_{pt}$ captures the total effect of low capitalization on firm performance. We have also run an IV estimate in which healthy firm performance is regressed on the share of zombies, and the latter is instrumented with $\overline{LowCap}_{pt}$. The sample only includes non zombie firms. The idea is that, by moving the T_D threshold of Figure 6, changes in the degree of capitalization induce changes in the share of zombies unrelated to local sectoral shocks that shift the distribution. As expected, we find a positive and statistically significant first stage coefficient. The second stage results confirm the previous analysis: exogenous shifts in the share of zombie firms have no effects on the performance of healthy firms. Although in line with the overall results, this analysis should be taken with a grain of salt, both because the first stage is not very powerful (F-test of around 6) and because the exclusion restriction might fail if, as discussed above, bank capitalization has direct effects on healthy firms performance through credit availability (although the previous results suggest that this is not the case). Finally, as explained above, we have used a measure of banks weakness based on the share of credit in the pre-crisis period (see equation 4). Results, reported in appendix Table A8, are very similar.

Overall, these results indicate that banks' capitalization does not affect the performance of healthy firms. The fact that low bank capital induces a higher growth of zombie firms is consistent with the findings of the previous section, that weaker banks lend more to zombies. From this perspective, zombie lending does affect outcomes. However, this does not hurt the healthy firms. This finding too is consistent with the fact that we found no negative effects of banks capitalization on the supply of credit to healthy firms. Our results therefore confirm one finding of the previous literature, that weaker banks extend credit to zombie firms. But they contradict the other finding, arguably more important, that this has negative consequences for healthy firms and, through this, on aggregate growth.

Note that our sample ends in 2013, and thus does not include the recovery years. This may be relevant, because some of the negative economic consequences of zombie lending are more likely to be felt when the recession is over, and healthy firms increase their demand for credit because they start investing again. During the recession, instead, keeping firms alive (even if non-viable) can cushion the negative general equilibrium effects of aggregate demand failures, and through this channel mitigate the adverse economic effects of an inefficient allocation of credit.

5.2 Firm failure

The previous regressions focus on the intensive margins, that is, firm's growth conditional on survival. But zombie lending also affects the extensive margin, since the banks' financing decisions determines firms' survival.[17] In fact, the term "zombie" is meant to indicate a non viable firm that survives only thanks to bank lending. To analyze the effects on the survival probability, we estimate the following regression:

$$F_{ipt} = \gamma_0 + \gamma_1 \overline{LowCap}_{pt} + \gamma_2 Z_{ipt} * \overline{LowCap}_{pt} + \gamma_3 Z_{ipt} + Dummies_{ipt} + \nu_{ipt} \qquad (5)$$

where F_{ipt} is a dummy variable equal to 1 if firm i in sector-province p exits through a bankruptcy procedure in year t.

The Firms Register reports the status of firms, signaling those failed or undergoing a legal procedure due to financial distress, typically leading to failure. We focus on failure, rather than overall exit, because the latter also includes voluntary firm closures without financial distress, ie., paying out all liabilities. These are cases in which the entrepreneur decides to close the firm, rather than being forced to shut down due to lack of credit. Instead, we want to focus on episodes in which the closure event is related to financial distress, and therefore to access to credit. We use as year of failure the last year in which we observe the firm in the dataset, that is, the last year in which the firm compiles its balance sheets. One problem is that the failure date is often after this year, as legal procedures take time to be implemented. For example, of the firms for which we last observe the balance sheets in 2008 and that exit through failure, 20% report as year of failure 2010, 10% 2011 and 7.6% 2012. This implies that, for the most recent years, we are underestimating the number of true failures, as we only have information up to 2013 To have a uniform definition of failure, independently from the year in which we last observe

---

[17]An additional channel could occur through entry, if zombie lending depresses firms' entry. Differently from the exit analysis, that can be carried out at the firm level accounting for the zombie status, we do not observe potential entrants. In a series of unreported regressions, we have performed the analysis at the aggregate province-year-sector level, regressing observed entry rates on $\overline{LowCap}$. We did not find any robust correlation between entry and banks capital ratios.

balance sheets, we only consider firms for which failure is within two years of the last year in which we observe the balance sheets and use data up to 2011. During the crisis years the overall failure rate is 2.9%; it decreases to 2% for non-zombies and increases to 7% for zombies. We expect that low capitalized banks reduce the failure rate of zombies ($\gamma_2 < 0$) at the expenses of healthy firms ($\gamma_1 > 0$).

We start with a linear probability model, as probit models are problematic to estimate with a large number of fixed effects. As before, we cluster standard errors at the province-sector level. Table 6 reports the results. In column (1) we use separate year and province-sector fixed effects. We find that $\gamma_1 = 0.444$ and significant at 5%, which implies that a larger share of undercapitalized banks increases the failure rate of non zombies. The effect is opposite for zombies: $\gamma_2 = -1.407$. Moreover, we reject the null hypothesis that $\gamma_1 + \gamma_2 = 0$, meaning that low capitalized banks decreases not only the relative but also the absolute failure probability of zombies.[18] The relative effect on zombies is very similar (statistically identical) in column (2), where we control for province-sector-year fixed effects, signalling that reverse causality is not likely to be an issue. Finally, in column (3) we estimate a probit model using the more parsimonious dummy specification, that is, with separate year and province-sector dummies. The marginal effects fully confirm the results of the linear probability model. In terms of the magnitude of the effects, the estimates of column (1) imply that increasing the capital ratio of all banks above the median would increase the failure rate of zombies by 0.4% and decrease that of non zombies bY 0.2%. This represents a reduction of approximately one tenth in the failure rate of healthy firms in the period.

As before, we have performed the analysis replacing $\overline{LowCap_{pt}}$ with $\widehat{LowCap_{pt}}$ as defined in equation refeq:lowcaphat). Table A9 in the appendix shows that the results change only marginally.

5.3 Productivity dispersion

We now turn to a third implication of zombie lending: the misallocation of credit increases the dispersion of productivity across firms. In fact, when banks lend relatively more to zombies, they increase both the relative chance of survival and the size of their operations, possibly at the expenses of healthy firms. TFP dispersion has become the standard measure of misallocation since the seminal contribution of Hsieh & Klenow (2009) who, following Foster et al. (2008), distinguish between physical TFP (computed on physical quantities) and revenue TFP (computed on revenues). In their model, monopolistic competition implies that, even if firms are heterogeneous in their physical TFP, revenue TFP

---

[18]Results are confirmed when we add sector-year and province-year fixed effects.

should be equalized across firms, as more efficient firms expand their scale of operation, thus decreasing pricing and, through this, revenue TFP. This process is inhibited by frictions that prevent the efficient allocation of inputs of production: the higher the frictions, the more dispersed is revenue TFP. In our case, the friction is an inefficient allocation of credit to low productivity firms. We thus assess whether zombie lending is associated with an increase in (revenue) TFP dispersion.

We compute revenue TFP (TFPR from now on) at the firm level assuming a constant return to scale Cobb-Douglas production function of the form $Y = TFPR * L^\alpha * K^{1-\alpha}$ where Y is value added, L labor and K the capital stock. We estimate the labor coefficient as the labor share at the sectoral level: $\alpha = \frac{wL}{Y}$, which varies between a maximum of 0.66 in Vehicles to a minimum of 0.35 in Electricity, gas and water. The labor input is measured as the wage bill and the capital input is computed using the permanent inventory method. We first compare the TFPR of zombies and non zombies. As expected, we find that the average log TFPR is substantially higher in healthy firms, with a log difference of almost 0.5. There is also evidence that the dispersion is higher among zombies firms: 0.71 against 0.61 for non zombies. Reallocating inputs from zombies to non zombies, therefore, should reduce the dispersion.

We start by analyzing the relationship between the share of zombies and TFPR dispersion. Specifically we estimate the following regression:

$$SD(TFPR)_{ipt} = \lambda_0 + \lambda_1 ShZ_{ipt} + \lambda_2 \Delta TFPR_{ipt} + Dummies_t + Dummies_{ip} + \eta_{pt} \quad (6)$$

The dependent variable, $SD(TFPR)_{ipt}$, is the standard deviation of TFPR at the sector-province-year level, where TFPR is computed as explained above. If zombies are a source of misallocation, we should expect that the higher their share the higher TFPR dispersion. In this specification we can only include separate dummy variables for the province-sector and for the year, since in the fully saturated model with province-sector-year fixed effects the coefficient of interest λ_1 cannot be identified. To control for shocks at the province-sector-year level, we include average TFPR growth at that level, ΔTFP_{ipt}. Descriptive statistics for TFPR dispersion and average TFPR growth at the province-sector-year level are in Table A6, Panel B.

Table 7 reports the estimates. To account for measurement error due to the fact that in some province-sector-years we have a small number of firms, in column (1) we exclude observations in which the standard deviation is computed on less than 10 firms. In column (2) we keep all province-sector-years, but weight them according to the number of firms contained in it. Consistent with the view that zombies are a source of misallocation, we find a positive correlation between the share of zombies and TFPR dispersion. In terms of magnitude, taking the estimate of Column (2), an increase in the share of zombies of one

standard deviation (0.191) would increase the standard deviation of the province-sector by 0.016, approximately 2.6% of it average value.

The problem with this regressions is that the causal interpretation rests on the assumption that changes in the share of zombies are orthogonal to the dispersion of TFPR. This is not an uncontroversial assumption. For example, since the seminal work by Lilien (1982), a large literature has argued that negative shocks can affect both the first and the second moment of the productivity distribution and that recessions are periods in which the dispersion of performance increases (Davis & Haltiwanger 1992, Bloom 2009). Moreover, we are interested in the extent of misallocation due to banks' lending choices, rather than to zombies in general. To directly test for the impact of banks' weakness on misallocation, we substitute ShZ with is the share of credit originated by banks with capital ratio below the median, $\overline{LowCap}_{ipt}$. As argued above, this variable is likely to be exogenous with respect to local conditions, and directly capture the health of the banking sector at the local-sectoral level. The estimates, reported in column (3) and (4) of Table 7, yield no evidence that banks' capital had any impact on misallocation during the crisis: the coefficient λ_1 is always negative, but very small and statistically insignificant. As an additional check, we have also run IV regressions in which the share of zombies is instrumented with $\overline{LowCap}$. As before, the first stage is weak so that in the second stage no significant effect of the share of zombies emerge. A weak first stage signals that the effects that we found on the extensive margins are too small to induce sufficient variation in the share of zombies to estimate the parameter.

Nevertheless, one can argue that what really matters is the interaction between the banks' capital ratio and the presence of zombies. That is, weak banks misallocate credit only if a market is populated by zombies: in sector-province with strong firms, there is no scope for diverting credit to unhealthy firms. To test this implication, we run the following regression:

$$
\begin{aligned}
SD(TFPR)_{ipt} = \lambda_0 + \lambda_1 \overline{LowCap}_{ipt} + \lambda_2 \Delta TFPR_{ipt} + \lambda_3 \overline{LowCap}_{ipt} * ShZ_{ipt} + \\
+ \lambda_4 ShZ_{ipt} + Dummies_t + Dummies_{ip} + \eta_{pt}
\end{aligned}
\tag{7}
$$

and test the hypothesis that the interaction coefficient λ_3 is positive. Of course, this specification has to be taken with some caution, as it is subject to the endogeneity issues of the share of zombies explained above. The results are in the last two columns of Table 7. First, the share of zombies itself is not significant anymore while that of $\overline{LowCap}_{ipt}$ is negative and significant, implying that, in the absence of zombies, low capitalization decreases TFPR dispersion. The interaction between $\overline{LowCap}_{ipt}$ and the share of zombies always has a positive and significant impact on the dispersion of TFPR, as expected. This means that, during the crisis, the combination of a larger population of

zombies and of weaker banks was positively related to the dispersion of TFPR. Given that $\partial SD(TFPR)_{ipt}/\partial \overline{LowCap}_{ipt} = \lambda_1 + \lambda_3 ShZ_{ipt}$, using the estimate of the last column we find that an increase in $\overline{LowCap}$ increases dispersion if the share of zombie firms is above 22%, which happens in around 44% of the province-sector-years. This indicates that low bank capitalization increases TFPR dispersion only in the presence of a fairly large population of zombies.[19] All in all, therefore, we conclude that banks low capitalization is responsible for only a modest misallocation of resources, measured in terms of TFPR dispersion. This is in line with some recent analyses of the evolution of misallocation in Italy at the aggregate level, which find that, if anything, it has slightly decreased during the crisis (Calligaris et al. 2016, Linarello & Petrella 2016). Again, all results are confirmed when using the indicator of banks weakness based on the pre-crisis credit shares (see appendix Table A10).

6 An Evaluation of the Aggregate Effects of Lowly Capitalized Banks

Putting all the pieces together, what would be the aggregate effects of recapitalizing the banking system so as to reduce the extent of zombie lending? In this section we propose a simple, stylized framework that allows us to compute some bounds on the answer to this question. The thought experiment is to inject capital in weaker banks, so that all banks with a capital ratio below the median reach the median itself. In other words, following the exercises of the previous section, we inject capital so that the value of the variable $\overline{LowCap}$ goes from an average of 0.241 to zero. Taking the level of banks' capitalization as of December 2012, this amounts to a capital injection of approximately 4 billions. We want to quantify the effect of this capital injection on aggregate growth during the crisis, based on the previous estimates.

6.1 A Simple Evaluation Scheme

Define Y^{NZ} as the average product of one unit of input in non-zombie firms. The units can be both firms (extensive margin) or workers/capital (intensive margin). Assume that a zombie's average product is $Y^Z = \theta Y^{NZ}, \theta \in [0, 1]$, where $\theta = 0$ is the case in which zombies are totally unproductive and $\theta = 1$ if zombies are as productive as non-zombies.

Consider first the case in which the unit is a firm, so that Y^{NZ} is the average output of non-zombies. Assume that there are n^{NZ} non-zombies and n^Z zombies. Total output

---

[19]The weak correlation between bank capitalization and TFPR dispersion is confirmed by the fact that, when we increase the set of dummies including sector-year and province-year fixed effects, we tend to loose statistical significance.

is then

$$Y = Y^{NZ} * n^{NZ} + Y^Z * n^Z = Y^{NZ} * (n^{NZ} + \theta * n^Z). \quad (8)$$

We want to compute the effect of recapitalizing banks so that they are all above the median level of the capital ratio in terms of firms' failure using the estimates of equation (5), as we are focusing on the extensive margin. The counterfactual output is

$$Y^{CF} = Y^{NZ} * (n^{NZ}(1 - \delta^{NZ}) + \theta * n^Z(1 - \delta^Z)) \quad (9)$$

where, δ^S, $S = Z, NZ$ is the effect of bank recapitalization on the failure rate of zombies and non-zombies respectively (so that $(1 - \delta^S)$ is the effect on their survival rate). Using the notation of equation 5 we have: $\delta^{NZ} = \hat{\gamma}_1 * \Delta\overline{LowCap}$ and $\delta^Z = (\hat{\gamma}_1 + \hat{\gamma}_1) * \Delta\overline{LowCap}$, and by the previous computations $\Delta\overline{LowCap} = -0.241$. When δ^S is negative, the number of surviving firms in the counterfactual scenario increases relative to the actual number, and vice versa if positive. In particular, we found that recapitalizing banks decreases the failure rate of non-zombies and increases that of zombies.

Define $sh^{NZ} = n^{NZ}/(n^{NZ} + n^Z)$ as the share of non-zombies firms and symmetrically for sh^Z. The growth rate of output in the counterfactual scenario relative to actual output is:

$$\frac{Y^{CF} - Y}{Y} = \frac{-sh^{NZ}\delta^{NZ} - \theta * sh^Z\delta^Z}{sh^{NZ} + \theta * sh^Z} \quad (10)$$

The first term in the numerator is the percentage increase in output coming from the increase in the number of non-zombie firms (provided that δ^{NZ} is negative), while the second term is the decrease coming from the exit of zombie firms, weighted by their relative productivity. The increase is maximal, and equal to δ^{NZ} itself, when $\theta = 0$, i.e., when zombies are totally unproductive, and minimal when $\theta = 1$. Even in this case, however, the increase in the capital ratio of banks can have a positive effect as long as $-sh^{NZ}\delta^{NZ} > sh^Z\delta^Z$. In particular, the fact that the share of non-zombies is four times as large as that of zombies magnifies the effect: even when the treatment has perfectly symmetric effects ($\delta^{NZ} = -\delta^Z$), output increases because there are more non-zombies so that the contraction in output due to zombies exit is more than compensated by the expansion in non-zombies.

From the descriptive statistics in Table A2, we have that the share of zombies during the crisis is $sh^Z = 0.19$; regression results in the first column of Table 6 deliver $\hat{\gamma}_1 = 0.444$ and $\hat{\gamma}_1 + \hat{\gamma}_2 = -0.963$, so that $\delta^{NZ} = 0.0011$ and $\delta^Z = 0.0023$. The increase in output for $\theta = 0$ is 0.11% and basically zero for $\theta = 0.5$. So, according to these numbers, the lower failure rate of healthy firms and the higher failure rate of zombies that would result from the capital injection increases output growth by at best 0.1% during the crisis.

For the intensive margin, we have shown that the effects on the growth of non-zombies are rather modest. Consistently, if we take the estimates for employment growth in the first column of Table 5, we obtain $\delta^Z = 0.012$ and $\delta^{NZ} = 0.0004$, so the increase in output is negligible for $\theta = 0$ and slightly negative for positive values of θ. We obtain similar results, if not even more negative, when we use capital and sales growth. Overall, the effect coming from the intensive margin is, in the best of cases, rather limited.

6.2   Discussion

Overall, this quantitative exercise suggests that recapitalizing the weaker banks would have a positive effect on output growth mainly or almost exclusively through the extensive margin. In our counterfactual exercises, a capital injection of 4 billions in the weaker banks would have increased yearly output growth by at most 0.1 during the crisis period 2008-2013. Under some scenarios, the effect could even be slightly negative, due to the reduction in the activity rate of zombies not counterbalanced by a corresponding increase in that of healthy firms. The mechanism operates by increasing the survival rate of healthy firms and increasing the failure rate of zombie firms. The reallocation effects on surviving firms are instead small.

During this same crisis period, yearly output growth was on average -3.7% in our sample of firms. Even under the most extreme assumption of zero productivity of zombies, therefore, zombie lending can explain less than 3% of this value. Thus, taken at face value, these results suggest that, while zombie lending played a role in aggravating the deep GDP contraction recorded by the Italian economy during the great recession, it is unlikely to be the key factor. Other developments, such as the drop in aggregate demand and the overall contraction of credit –rather than its misallocation to weak firms– are likely to be at the heart of the recession.

This result does not rule out the possibility that zombie lending could have a larger effect in slowing down the recovery after the recession. First, most of the effects play out through the extensive margins suggesting that credit misallocation might take time to display its full consequences. Failures and closures (as well as firm opening), require years to be implemented and our time span might be too short to capture these medium to long run effects. Second, in a deep recession such as the one that characterizes our period of analysis, zombie lending might be less harmful to growth than during a recovery. Mian et al. (2015) show that, in US states where foreclosures were easier to implement, the foreclosure rate was higher and the decline in aggregate demand stronger. This effect might be present for firms too. Reallocating productive factors from low productivity firms requires that there are more productive firms willing to use such assets. During the deep

recessionary period we analyze, however, even healthy firms suffered large demand drops and, therefore, their demand for inputs might have been unable to absorb those freed up by zombies. In such a scenario, hoarding factors in zombies might be less detrimental to growth than during "normal" times. If this were the case, the negative effects of zombie lending would be much larger during the recovery period, when good firms face more expansion opportunities and therefore express a higher demand for credit.

7   Concluding remarks

This paper explored the consequences of under-capitalization of Italian banks during the Eurozone financial crisis, in the period 2008-13. We find that banks with low capital are more reluctant to cut credit to non-viable firms. The effect is only present during the crisis years and its aftermath, and it only concerns regulatory capital (and not other indicators of bank weakness). Capital requirements became more demanding during and after the crisis years, also in association with the transition of bank supervision from national to European authorities. Hence our results suggest that the misallocation of credit towards non-viable firms may have been a reaction to the tighter regulatory environment, as weaker banks attempted to reduce the risk of supervisory requests to boost their capital.

This misallocation of credit has important effects on the real economy. During the crisis years, bank capitalization affects the composition of bankruptcies. In province-sectors where lending is predominantly done by weaker banks, zombie firms are more likely to survive, and healthy firms are more likely to fail. We also observe a greater dispersion of TFP if banks are weaker, although this effect is present only if the share of zombie firms in the province-sector-year is sufficiently large.

Nevertheless, we find no evidence that the growth of existing healthy firms is hurt by bank weakness. We do find that bank weakness induces a lower growth rate of healthy firms relative to zombies, in line with the previous literature. But this happens because weak banks allow zombies to grow faster (or more precisely to contract less). When this higher growth of zombies is taken into account, the absolute effect of bank under-capitalization on the growth rate of healthy firms is close to zero. There is also no evidence that bank weakness reduced the entry of new firms. A plausible interpretation of this finding is that weak banks lend more to non-viable firms, and this mitigates the local adverse aggregate demand externalities, partly offsetting the other negative spillovers effects of zombie firms. This interpretation is also consistent with our finding that under-capitalized banks extend more credit to zombies (compared to stronger banks), but do not reduce credit to healthy firms.

All in all, this suggests that bank-undercapitalization may be costly in terms of mis-

allocation of capital and productive efficiency in the medium term, but cannot be blamed for aggravating or prolonging the recession induced by the Eurozone financial crisis. Of course, this conclusion cannot be extrapolated to the recovery phase, since our sample ends in 2013 and Italian GDP growth was negative until the last quarter of 2014.

Figures and Tables

Figure 1: Credit Growth and GDP Growth in Italy
The figure shows the growth of credit by banks to non-financial firms and GDP growth in Italy between 2004 and 2014. Credit is from Supervisory reports, GDP growth is from National Statistics (ISTAT).

Figure 2: Credit to Zombie and to Non-Zombie Firms
The figure shows log of granted credit to zombie and to non zombie firms used in our sample. Zombie firms are defined as those that in a given year has the 3 years moving average of ROA below PRIME, and leverage above the median leverage in year 2005 of firms that had the moving average of ROA below the prime rate in at least one year between 2004 and 2005 and that exited the market in 2006 or 2007 due to default or liquidation. The sample include non-financial firms borrowing from at least two Italian banks between 2004 and 2013. Data on credit are from the Credit Register. Data on firm characteristics are from the Firm register.

Figure 3: Leverage of Firms

(a) Whole sample

(b) Firms Exiting and with Roa<Prime Rate
Panel a shows the distribution of leverage (the ratio of debt from banks and from other financiers, excluding trade debt and debt towards shareholders, to total assets) for the whole sample of firms included in the firm register. Panel b shows the distribution of leverage of firms with the moving average of ROA below the prime rate in at least one year between 2004 and 2005 and that exited the market in 2006 or 2007 due to default or liquidation. The threshold on leverage used to define zombie firms is the median of this distribution. Data are from the year 2005.

Figure 4: Share of zombie firms and GDP growth

The figure plots the share of zombie firms (left scale) and GDP growth (right scale). Zombie firms are those with the 3 years moving average of ROA below PRIME, and leverage above 40% (see the main text and Figure 3). Data on firms are from the firm register (CERVED), GDP growth is from National Statistics (ISTAT).

Figure 5: Share of zombie firms by quartiles of bank capital
The figure shows the share of zombie firms by quartiles of bank capital. The share is computed using bank-firm relationships from the Italian Credit Register. Bank capital is the ration of regulatory capital to risk weighted assets. Data cover the period 2004-2013.

Figure 6: The effect of a common shock on zombies and non zombies
The figure plots two normal distributions with unit variance and mean $\mu_L = 4$ and $\mu_H = 5$, respectively. T_Z is the threshold to be classified zombie and T_D is the threshold for exit.

Figure 7: Difference in non zombies vs. zombies average performance
(a) Relative performance and aggregate shocks (b) Relative performance and share of zombies

The graphs report the difference in the conditional mean of zombies and non zombies, $\mu^{NZ} - \mu^{Z}$. In Panel a it is plotted against the aggregate shock $s = 0, 0.01..., 3$, which determines the leftward shift in the performance distribution, as illustrated in Figure 6. In Panel b it is plotted against the share of zombies implied by the leftward shift in the distribution shown in Panel a.

The table shows regressions of the change in the log of credit granted (credit commitments) on the dummy for "zombie" firms (Z), the dummy for banks with capital ratio below the median (LowCap) and their interactions. The median capital ratio is computed on the distribution as of 2008. The change in the log of credit granted is computed as the difference between total credit granted to the firm by the bank in period t and period $t + 1$. Firm and bank level controls are measured as of year t. The dummy for a zombie firm equals one if both a) the firm's ROA (2 years moving average) is below the prime rate (2 years moving average); and b) the firm's leverage is above the median leverage, as of the end of 2005, computed on the sample of firms that had ROA below the prime rate in at least 1 year between 2004 and 2005 and which exited in 2006 or 2007. The capital ratio is the ratio of bank regulatory capital and risk weighted assets. Liquidity ratio is the ratio of cash and government bonds to total assets; Interbank ratio is the ratio of interbank deposits and repos with banks (excluding those with central banks) and total assets; ROA is the ratio of profits to total assets. Bank size is the log of total assets. The sample includes years between 2008 and 2012 (the change in log credit in the last year is computed between 2012 and 2013). Column 5 includes bank-firm relationships in which some credit is collateralized (i.e. the share of collateralized credit is positive). Column 6 includes firm*bank relationships in which no credit is collateralized (i.e. the share of collateralized credit is zero). Standard errors double clustered at the bank and firm level in parentheses. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$

Column 1 to 3 of the table shows regressions of a dummy equal to 100 if the bank classifies the loan as non-performing on the dummy for "zombie" firms (Z), the dummy for banks with capital ratio below the median (LowCap) and the dummy for the crisis period (crisis), and their interactions. The dummy Bad Loan, column (1), equals 100 if the bank classifies the loan as a bad loan, and zero otherwise, between year t and year t+1; the dummy Non-Per, column (2), equals 100 if the bank classifies the loan as non-performing and zero otherwise, between year t and year t+1; the dummy Past-Due, column (3), equals 100 if the bank classifies the loan as past-due and zero otherwise, between year t and year $t+1$. Column 4 show regressions of the dummy low capital bank on the level of the interest rate on credit lines in year $t+1$. Column 5 and 6 show regressions of the dummy low capital bank and its interactions with the share of credit of the bank on the change in the log credit granted between year t and year $t+1$. These regresisons represent a test of evergreening. All regressions include firm*year fixed effects and bank fixed effects (the same specification as in column (4) of Table 1), the share of total credit to the firm grant by the bank and the share of credit line out of total credit to the firm by the bank. Bank level controls are defined in the notes to table 1. The sample includes yearly data between 2008 and 2012 (for the classification of loans as bad, non performing, past-due, we consider data from 2009 to 2013). Standard errors double clustered at the bank and firm level in parentheses. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$

The table shows regressions of the change in the log of credit granted (credit commitments) on the dummy for "zombie" firms (Z), the dummy for banks with capital ratio below the median (LowCap) and their interactions. The median capital ratio is computed on the distribution as of 2008. The change in the log of credit granted is computed as the difference between total credit granted to the firm by all banks in period t and period $t+1$. Bank level controls are averaged at the firm level using the share of credit of the bank as weight. Firm and bank level controls are measured as of year t. Bank level and relationship-level controls are averaged at the firm level using the share of credit of the bank as weight. The dummy for a zombie firm equals one if both a) the firm's ROA (2 years moving average) is below the prime rate (2 years moving average); and b) the firm's leverage is above the median leverage, as of the end of 2005, computed on the sample of firms that had ROA below the prime rate in at least 1 year between 2004 and 2005 and which exited in 2006 or 2007. Columns 1 to 3 include the same firms as those included in Table 1 (firms borrowing from at least two banks in both period t and t+1). Column 4 includes also single bank firms. Standard errors clustered at the firm level in parentheses. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$

R-squared	0.036	0.058	0.019	0.029	0.083	0.122

The table shows regressions of different measures of firm growth on banks' capital ratio $\overline{\text{LowCap}}$, defined as the average at the province-sector-year of a dummy equal to one for banks with a capital ratio below the median capital ratio. The average is computed using the share of credit in the province-sector-year as weights. The dependent variable is the delta log of the wage bill in column 1-2, of intermediate inputs in columns 3-4, of the book value of the capital stock in columns 5-6, of sales in columns 7-8, of TFP in columns 9-10. Odd columns include province-sector and year fixed effects, while even columns include province-sector-year fixed effects. $\beta_1 + \beta_2$ is the sum of the coefficients in the first two rows in the column. The sample includes yearly data form 2008 to 2013. Standard errors clustered at the province-sector level. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$.

The table shows regressions of a dummy equal to 100 for firms that go bankrupt on banks' capital ratio, so that all coefficients can be red as percentages. $\overline{\text{LowCap}}$ is the average at the province-sector-year of a dummy equal to one for banks with a capital ratio below the median capital ratio. The average is computed using the share of credit in the province-sector-year as weights. Z is a dummy for zombie firms. Odd columns include province-sector and year fixed effects, while even columns include province-sector-year fixed effects. The first two columns are OLS estimates, while column (3) is a probit estimate, with marginal effects reported. $\gamma_1 + \gamma_2$ is the sum of the coefficients in the first two rows in the column. The sample includes yearly data form 2008 to 2011. Standard errors clustered at the province-sector level. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$.

R-squared	0.825	0.872	0.824	0.871	0.826	0.872

The table shows regressions of the standard deviation of TFP at the province-sector-year level on the share of zombies and banks' capital ratio. Specifically, ShZ is the share of firms that are classified as zombies in the province-sector-year and $\overline{\text{LowCap}}$ is the average at the province-sector-year of a dummy equal to one for banks with a capital ratio below the median capital ratio. The average is computed using the share of credit in the province-sector-year as weights. TFP growth is Delta log of the average TFP at the province-sector level. Columns 1, 3 and 5 exclude province-sector-years with less than 10 firms. Columns 2, 4 and 6 include all province-sector-years but weight them according to the number of firms. All regressions include year and province-sector fixed effects. The sample includes yearly data form 2008 to 2013. Standard errors clustered at the province-sector level. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$.

A   Appendixes

A.1   A general condition for ...

Consider the effect of a shift to the left in the distribution $F(X)$ depicted in Figure 6. We want to know how this shift affects the difference between conditional means, $\mu^{NZ} - \mu^{Z}$, where:

$$
\begin{aligned}
\mu^{NZ} &= \frac{1}{1 - F(T_z)} \int_{T_z}^{\infty} x \, dF(x) \\
\mu^{Z} &= \frac{1}{F(T_z)} \int_{-\infty}^{T_z} x \, dF(x)
\end{aligned}
\tag{11}
$$

Note that this question is equivalent to asking how $\mu^{NZ} - \mu^{Z}$ is affected by a change in the threshold T_z. By (11) we have:

$$
\begin{aligned}
\frac{\partial \mu^{NZ}}{\partial T_z} &= \frac{f(T_z)}{1 - F(T_z)} (\mu^{NZ} - T_z) \\
\frac{\partial \mu^{Z}}{\partial T_z} &= \frac{f(T_z)}{F(T_z)} (T_z - \mu^{Z})
\end{aligned}
$$

so that

$$
\text{Sign} \; \frac{\partial(\mu^{NZ} - \mu^{Z})}{\partial T_z} = \; \text{Sign} \; \left\{ F(T_z)\mu^{NZ} + [1 - F(T_z)]\mu^{Z} - T_z \right\}
\tag{12}
$$

Let $\mu = F(T_z)\mu^{Z} + [1 - F(T_z)]\mu^{NZ}$ denote the unconditional mean of x. Equation (12) can then be rewritten as:

$$
\text{Sign} \; \frac{\partial(\mu^{NZ} - \mu^{Z})}{\partial T_z} = \text{Sign} \; \left\{ (\mu^{NZ} - \mu) - (T_z - \mu^{Z}) \right\}
$$

It is easy to verify that for a uniform distribution this implies $\frac{\partial(\mu^{NZ} - \mu^{Z})}{\partial T_z} = 0$. More generally, a necessary and sufficient condition for $\frac{\partial(\mu^{NZ} - \mu^{Z})}{\partial T_z} < 0$ is that

$$
(\mu^{NZ} - \mu) < (T_z - \mu^{Z})
\tag{13}
$$

A.2 Descriptive statistics and additional results

Table A1: Descriptive statistics of firms

	Mean	Median	25pct	75pct	S.D.	N
Non-Zombie Firms

Assets (000 Euros)	9,414	1,999	896	5,049	119,134	582,406
Zombie Firms						
Leverage	56.84	52.89	45.88	63.58	15.06	119,488
ROA	-1.34	1.09	-3.35	3.35	7.98	119,488
EBITDA/Int Exp	-0.45	0.48	-1.36	1.44	4.16	118,875
Cash Hold / Assets	3.18	0.94	0.23	3.30	6.15	109,909
Liquidity / Assets	9.11	3.20	1.05	8.62	65.19	119,463
Assets (000 Euros)	12,896	3,156	1,245	8,653	79,031	119,488

The table shows descriptive statistics of firms according to "Zombie" status, before the crisis (2004-2008 - Panel A) and after the crisis (2009-2012- Panel B). A zombie firm in a given year has the 3 years moving average of ROA below PRIME, and leverage above the median leverage in year 2005 of firms that exited the market in 2006 or 2007 due to default or liquidation. Data are from the Firm Register (Cerved) available at annual frequency from firms' balance sheets. Leverage is total financial debt over total assets; ROA is profits to assets ratio; Ebitdta/Int Exp is the ratio of Earnings before interest taxes depreciation and amortization to interest expenses; Cash Holdings to Assets is the ratio of cash and cash equivalents to total assets; Liquidity to Assets is the share of liquidity and short term assets to total assets.

Share credit line	24.16	11.11	3.50	30.71	30.50	2,287,690

The table shows descriptive statistics of the variables used in the regressions, relative to the estimating sample. The statistics are taken over the distribution of firm-bank-year observations. Data on credit and on bank-firm relationships are from the Italian Credit Register. Data on firm characteristics are from the Firm Register. Data on bank characteristics are from the Supervisory Reports. The sample period includes bank-firm relationships at the year frequency between 2007 and 2013. Delta log credit is the yearly difference in log credit granted; D cut= 1 is a dummy equal to one if a credit relationship is severed in the next year; D Bad Loans is a dummy equal to 1 if the bank classifies a loan as bad loan between year t and $t+1$; D Non-Per if a dummy equal to 1 if the bank classifies a loan as non performing between year t and $t+1$; D Past Due is a dummy equal to 1 if the bank classifies a loan as past due between year t and $t+1$; LowCap is a dummy equal to 1 if the capital ratio is below the median capital ratio in the sample; Capital Ratio is the ratio of regulatory capital to risk weighted assets; D Cap Ratio< 9 is a dummy equal to 1 if the capital ratio is below 9 (the regulatory threshold is 8); LowCap yby is a dummy equal to 1 if the capital ratio is below the median capital ratio computed year by year; Tier 1 ratio is the ratio of Tier 1 capital to risk weighted assets; D Tier 1 Ratio < 5 is a dummy equal to 1 if the Tier 1 Ratio is below 5 (the regulatory threshold is 4); D Tier 1 Ratio <Median is a dummy equal to 1 if the Tier 1 Ratio is below the median Tier 1 ratio in the sample; Liquidity ratio is the ratio of cash plus government securities to total assets; Interbank ratio is the ratio of interbank deposits to total assets; ROA is the ratio of bank profit to total assets; Bank size is the log of total assets; Zombie is a dummy equal to 1 if the firm's ROA (2 years moving average) is below the prime rate (2 years moving average) and the firm's leverage is above the median leverage, as of the end of 2005, computed on the sample of firms that had ROA below prime rate in at least 1 year between 2004 and 2005 and which exited in 2006 or 2007. Zombie 2 is a dummy equal to 1 if the firm EBITDA to interest expenses ratio (2 years moving average) is below 1 and the firm's leverage is above the median leverage, as of the end of 2005, computed on the sample of firms that the ebit to interest expenses ratio below 1 in at least 1 year between 2004 and 2005 and which exited in 2006 or 2007; Zombie3 is the defined in the same way as zombie but it has the additional condition that revenues did not increase for the next consecutive years (this allows to define as non-zombies fast growing firms such as start-ups and the like; PC ROA-leverage (PC 1) is the principal components of the moving average of ROA and leverage, PC EBITDA/Int-Leverage is the principal component of the moving average of the EBITDA to interest expenses ratio and leverage. Share bank is the share of total credit to the firm by the bank; Share credit line is the share of overdraft loans out of total loans within the bank-firm relationship.

The table replicates the regressions in columns (4) (with firm*year and bank fixed effects) of Table 1 using alternative definitions of "zombie" firms. In column (1) the dummy for a zombie firm (Zombie 2) equals one if both a) the firm EBITDA to interest coverage ratio (2 years moving average) is below 1; and b) the firm's leverage is above the median leverage, as of the end of 2005, computed on the sample of firms with EBITDA to interest coverage ratio below 1 in at least 1 year between 2004 and 2005 and which exited in 2006 or 2007; in column (2) the dummy for a zombie firm (Zombie 2) equals one if a) the firm's ROA (2 years moving average) is below the prime rate (2 years moving average) - b) the firm's leverage is above the median leverage, as of the end of 2005, computed on the sample of firms that had ROA below the prime rate in at least 1 year between 2004 and 2005 and which exited in 2006 or 2007 - c) revenues did not increase for the next consecutive years (this allows to define as non-zombies fast growing firms such as start-ups and the like); in column (3) the continuous indicator for zombie firms PC 1 is the principal component of the moving average of ROA and leverage; in column (4) PC 2 is the principal component of the moving average of the EBITDA to interest coverage ratio and leverage. See the note to Table 1 for the definition of the other variables. Standard errors double clustered at the bank and firm level in parentheses. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$

The table replicates the regression in column (5) (with firm*year and bank fixed effects) of Table 1 using alternative definitions of 'banks strength. In column (1) the indicator of banks strength is a dummy equal to one if the capital ratio in a year is below the median capital ratio in that year; in column (2) is the continuous capital ratio; in column (3) is a dummy equal to one if the capital ratio is below 9 (the minimum regulatory threshold is 8%); in column (4) a dummy for banks with ROA below the median (LowCap); in column (5) a dummy equal to one if the bank has leverage (total assets to capital) above the median; in column (6) a dummy equal to one if the ratio of bad loans to assets is above the median. The median of all variables is computed on the distribution as of 2008. The sample includes years between 2008 and 2012 (the change in log credit in the last year is computed between 2012 and 2013). Standard errors double clustered at the bank and firm level in parentheses. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$

R^2	0.149	0.336	0.364	0.364

The table shows regressions of the change in the log of credit granted (credit commitments) on the dummy for "zombie" firms (Z), the dummy for banks with capital ratio below the median (LowCap) and their interactions. The median capital ratio is computed on the distribution as of 2004. The change in the log of credit granted is computed as the difference between total credit granted to the firm by the bank in period t and period $t + 1$. Firm and bank level controls are measured as of year t. The dummy for a zombie firm equals one if both a) the firm's ROA (2 years moving average) is below the prime rate (2 years moving average); and b) the firm's leverage is above the median leverage, as of the end of 2005, computed on the sample of firms that had ROA below the prime rate in at least 1 year between 2004 and 2005 and which exited in 2006 or 2007. The capital ratio is the ratio of bank regulatory capital and risk weighted assets. Liquidity ratio is the ratio of cash and government bonds to total assets; Interbank ratio is the ratio of interbank deposits and repos with banks (excluding those with central banks) and total assets; ROA is the ratio of profits to total assets. Bank size is the log of total assets. The sample includes years between 2004 and 2007. Standard errors double clustered at the bank and firm level in parentheses. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$

Table A6: Summary Statistics for the Effects of Zombie Lending

	Mean	Median	25pct	75pct	S.D.	N

TFP growth	-0.020	-0.017	-0.084	0.046	0.177	10,972

The table shows descriptive statistics of the variables used in regressions of the effects of zombie lending. Panel A reports growth rate of the wage bill, the capital stock, sales and TFP, all at constant prices, and a dummy equal to 1 if a firm fails. Panel B report indicators at the province-sector-year levels. Share of credit to zombie Firms is the share of credit that is granted to zombies in a given province-sector-year; CR below median is the share of credit extended by banks with a capital ratio below the median value of the banks' capital ratio; Share of zombies is the share of firms classified as zombies according to our preferred definition; Standard deviation of TFP and TFP growth are again computed at the province-sector-year level. Variables refer to the years 2008-2013.

R-squared	0.036	0.058	0.019	0.029	0.083	0.122

The table shows regressions of different measures of firm growth on the share of zombies at the province-sector-year level ShZ. The dependent variable is the delta log of the wage bill in column 1-2, of the book value of the capital stock in columns 3-4, of sales in columns 5-6. Odd columns include province-sector and year fixed effects, while even columns include province-sector-year fixed effects. $\beta_1 + \beta_2$ is the sum of the coefficients in the first two rows in the column. The sample includes yearly data form 2008 to 2013. Standard errors clustered at the province-sector level. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$.

The table shows regressions of different measures of firm growth on banks' capital ratio, $\widehat{\text{LowCap}}$, computed as the average at the province-sector-year of a dummy equal to one for banks with a capital ratio below the median capital ratio. The average is computed using the share of credit in the province-sector for the period 2004-2007 as weights. The dependent variable is the delta log of the wage bill in column 1-2, of the book value of the capital stock in columns 3-4, of sales in columns 5-6. Odd columns include province-sector and year fixed effects, while even columns include province-sector-year fixed effects. $\beta_1 + \beta_2$ is the sum of the coefficients in the first two rows in the column. The sample includes yearly data form 2008 to 2013. Standard errors clustered at the province-sector level. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$.

R-squared	0.016	0.020	0.038

The table shows regressions of a dummy equal to 100 for firms that go bankrupt on banks' capital ratio, so that all coefficients can be red as percentages. $\widehat{LowCap}$ is the average at the province-sector-year of a dummy equal to one for banks with a capital ratio below the median capital ratio. The average is computed using the share of credit in the province-sector for the period 2004-2007 as weights. Z is a dummy for zombie firms. Odd columns include province-sector and year fixed effects, while even columns include province-sector-year fixed effects. The first two columns are OLS estimates, while column (3) is a probit estimate, with marginal effects reported. $\gamma_1 + \gamma_2$ is the sum of the coefficients in the first two rows in the column. The sample includes yearly data form 2008 to 2011. Standard errors clustered at the province-sector level. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$.

Table A10: TFP dispersion and credit to zombies

R-squared	0.825	0.872	0.824	0.871	0.825	0.872

The table shows regressions of the standard deviation of TFP at the province-sector-year level on the share of zombies and banks' capital ratio. Specifically, ShZ is the share of firms that are classified as zombies in the province-sector-year and $\widehat{LowCap}$ is the average at the province-sector-year of a dummy equal to one for banks with a capital ratio below the median capital ratio. The average is computed using the share of credit in the province-sector for the period 2004-2007 as weights. TFP growth is Delta log of the average TFP at the province-sector level. Columns 1, 3 and 5 exclude province-sector-years with less than 10 firms. Columns 2, 4 and 6 include all province-sector-years but weight them according to the number of firms. All regressions include year and province-sector fixed effects. The sample includes yearly data form 2008 to 2013. Standard errors clustered at the province-sector level. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$.
